This programme is identified with the first effort to implement, as national policy, a strategy which accorded priority to the discovery of outbreaks and their containment, even if these activities meant some compromise in the pace of execution of the mass vaccination campaign. An important change of emphasis in the global strategy took place as a result, and, in supporting this change, WHO staff frequently cited the successful experience of the regional programme. In retrospect, however, when the relative contributions made by mass vaccination and surveillance-containment ("eradication-escalation") are weighed, the importance of surveillance-containment to the western and central Africa programme itself is less certain. When such measures were actually implemented late in 1968, the mass vaccination campaign had already reached some 60 million persons, more than half the population of the region, and a much higher proportion of those in the known endemic areas, to which the campaign had given priority. Endemic smallpox then remained in only a few of the countries, and where surveillance teams actively sought to discover and to contain outbreaks—as in Dahomey, Guinea, Sierra Leone and Togo—smallpox transmission had practically ceased, the remaining outbreaks being small and in isolated rural areas. The strategy was not employed in northern Nigeria, then the principal focus of smallpox. There, programme staff undertook to contain outbreaks only in areas in which the mass vaccination campaign had been completed.

Thus although the rapid demise of smallpox in western and central Africa was impressive, and the success of the programme attributed to the new strategy, the well-executed mass vaccination campaign using freeze-dried vaccine probably played the more decisive role.

In this region, as well as in most of Africa south of the Sahara, the interruption of smallpox transmission proved to be more straightforward and less difficult than in Indonesia and the Indian subcontinent. In contrast to the Asian countries, the population density in Africa was lower, population movement was less, vaccination was usually more readily accepted, and many villagers, by tradition, isolated smallpox patients. When the comparatively simple surveillance-containment methods used in Africa were employed in Asia, the results proved disappointing. In Bangladesh, India and Pakistan, in particular, whose populations had generally higher levels of vaccinal immunity than

those of African countries, surveillance and containment measures failed to make a significant impact on the disease until the methods were substantially modified and strengthened.

As had been hoped, the programme in western and central Africa served to strengthen the foundation for disease reporting and preventive services in all the countries concerned, but with only 5 years of operational experience the endeavours could not be fully institutionalized. Thus, in 1976, when it became necessary to certify that eradication had been achieved, special programmes had to be organized to permit certification (see Chapter 25).

Subsequent chapters describe eradication programmes in other countries of Africa, which, with some notable exceptions, consisted largely of mass vaccination campaigns but which succeeded in eliminating smallpox with surprising rapidity.

### INTRODUCTION

Eradication programmes in a group of contiguous countries of western and west-central Africa began in 1967 and 1968, with support primarily from the USA and technical assistance provided by the United States Communicable Disease Center. East of this area lay two of Africa's largest countries—Zaire and the Sudan (Fig. 18.1). (Zaire was named the Democratic Republic of the Congo from 1960 to 1971, but its present name is used throughout this chapter for convenience.) Their combined population in 1967 amounted to only about 33 million, but their total area (approximately 4.85 million square kilometres) was equivalent to that of the whole of Europe, excluding the European part of the USSR. Transport and communica-

tions in both countries were poor and the terrain was difficult. Zaire was in WHO's African Region and the Sudan in its Eastern Mediterranean Region.

In the African Region, Zaire strategically had the highest priority for the allocation of WHO resources. Smallpox was endemic throughout the country; in 1967, it accounted for one-third of the total number of cases reported in the countries of central, eastern and southern Africa. Indeed, of all the African countries, only Ethiopia was to record more cases after the Intensified Smallpox Eradication Programme began. Vaccinal immunity was low throughout the country. Along its lengthy western, northern and southern borders lay 5 countries which had interrupted smallpox transmission or seemed close to doing so—Angola, the Central African Re-

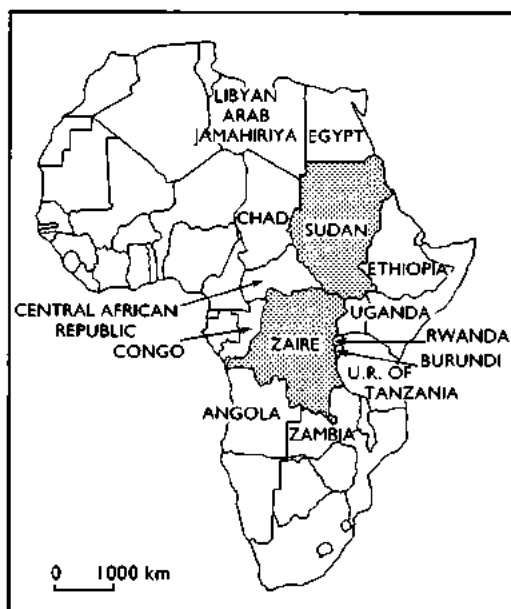

Fig. 18.1. Sudan and Zaire and adjacent countries.

public, the Congo, the Sudan and Zambia. In all, these 5 countries reported 686 cases in 1965 and only 66 in 1966. Because of the frequent movement of travellers across the Zairian border, importations of smallpox were inevitable. When they occurred, the detection and control of the outbreaks, especially in border areas, were problematic owing to the paucity of health services and the difficulties of travel and communication.

The status of smallpox in the Sudan was entirely different. A mass vaccination campaign using freeze-dried vaccine had been conducted throughout the central and northern parts of the country between 1961 and 1963. The Sudan reported no cases at all in 1963, 1964 and 1966; in 1965, 69 cases occurred as a result of importations. However, in the country's 3 southern provinces, which had a population of about 2.5 million, government health services were restricted to the larger towns because of a protracted, devastating civil war. Thus, the status of smallpox in the extensive rural areas of the south could not be known with certainty. Even so, there was hope that the disease might not be present. No cases were being detected in the towns, no imported cases from this area were being found in adjacent countries despite the considerable numbers of migrants and travellers, and reports reaching WHO from revolutionary groups in the south indicated

that no known cases of smallpox were occurring. Moreover, the area was sparsely populated, making the sustained transmission of smallpox difficult.

Agreements to undertake eradication programmes were signed by the Zairian government in November 1966 and by the Sudanese government in April 1967. In both countries, the plans called for the administration of BCG (antituberculosis) vaccine to children and adolescents at the same time as the whole population was being vaccinated against smallpox. It was the first time a national programme had been attempted which incorporated the simultaneous administration of the two vaccines. The concept seemed sensible but, logistically, there were problems because the BCG vaccine had to be administered intradermally. In Zaire, inoculation was performed at collecting points, and there it eventually proved feasible to use the jet injectors for both smallpox and BCG vaccination. In the Sudan, however, the jet injectors were not practical because in many areas the population was not accustomed to assembling at collecting points. Smallpox vaccine was therefore administered with the bifurcated needle by vaccinators moving from house to house, but the administration of BCG vaccine by syringe and needle was too cumbersome to permit this procedure. Accordingly, programme staff endeavoured, without great success, to gather the children at assembly points.

In addition to the problems inherent in administering two vaccines rather than one, both programmes faced other difficulties, including those of conducting campaigns in large areas in which civil disorder was prevalent. Moreover, in Zaire, trained manpower in all sectors of government was scarce, communication facilities were few, the network of roads was limited and in poor repair, and travel through dense tropical rain forests was difficult. However, a highly effective vaccination campaign began to take shape there in 1968, and by July 1971 a carefully assessed systematic programme had been completed throughout the country during which smallpox vaccine was given to more than 24 million persons and BCG vaccine to more than 11 million. The last recorded case of smallpox appears to have occurred in June 1971.

Because of the lack of trained staff and the size of the country, organized surveillance was not developed until after the completion

of the vaccination campaign, and thus few outbreaks were investigated. However, an excellent surveillance system subsequently evolved, which served to strengthen the existing health structure and to confirm the absence of smallpox. Between 1970 and 1986, more than 400 cases of monkeypox, a disease clinically resembling smallpox (see Chapter 29), were eventually discovered.

The hope that the Sudan would remain free of smallpox was shattered late in 1968, when increasing numbers of cases began to be detected among persons living in the war-stricken south near the Ethiopian border and among migrant agricultural labourers from that area. Meanwhile, a mass vaccination campaign had been initiated in provinces in the central part of the country, but it was disrupted by the occurrence of cholera in 1970-1971. Although the investigation and containment of all suspected cases in a country believed to be smallpox-free were considered by WHO to be of high priority, no programme for the purpose was developed. Smallpox spread across the country in 1970 and 1971. In only 2 African countries that were free of smallpox in 1967 did endemic smallpox become re-established, and the Sudan was the first of these. Finally, in January 1972, a Sudanese medical officer took the initiative of developing a surveillance-containment programme which interrupted transmission with such unexpected rapidity that WHO consultants recruited to help to strengthen the operation arrived just as the last cases were occurring. Thereafter, Sudanese surveillance teams assisted Ethiopian staff in search activities along the border, as well as in Ethiopia itself.

## ZAIRE

### Background

Zaire, Africa's third largest country, is mostly low plateau (average altitude, 500 metres), comprising the central basin of the Zaire (formerly Congo) river and its tributaries. Higher plateaux surround the low plateau, rising to mountains in the east. Extending 2300 kilometres from east to west, much of the country is covered by dense tropical rain forest, giving way at higher elevations to wooded savanna and grassland. Throughout central Zaire, temperatures are uniformly high (24-27 °C), as is the humidity.

In 1967, almost 90% of the inhabitants were rural dwellers, many living in clusters of 10-20 houses along roads or tracks. Of the 233 000 kilometres of roads, only 3000 kilometres were of the all-weather asphalt type. In extensive riverine tropical rain forest areas, villages could be reached only by boat or on foot. Kinshasa, the capital (then called Léopoldville), was the largest city in tropical Africa (population, about 1 million), but there were 9 other cities in Zaire with populations of 100 000 or more. Telegraphic and postal services were limited and unreliable; communication among the various tribal groups, speaking more than 200 different languages and dialects, posed a problem.

Zaire became independent in June 1960 but within a week, an army mutiny and threatened secession brought in a United Nations peace-keeping force, which remained for 4 years. A large-scale United Nations technical assistance programme was also initiated and continued in operation until 1969. With the departure of the United Nations forces, rebellion recurred throughout the north-eastern provinces and sections of those in west-central Zaire. After the autumn of 1965, the conflict gradually subsided, but security in parts of the country remained a problem for several years. During the long period of fighting, roads and bridges were destroyed or deteriorated, and the structure of the health services was greatly weakened. Not surprisingly, few persons were vaccinated against smallpox during this time.

Trained personnel throughout the country were proportionately far fewer in Zaire than in most African countries. Primary education had been made widely available during the 1950s, but few people had been educated in secondary schools or institutions of higher learning. There were, for example, no national physicians in 1960, only 88 in 1965 and only 221 in 1970.

Because of the dearth of educated national staff, United Nations and bilateral technical assistance programmes provided many of the necessary senior and middle management personnel for the government. In the health sector, there were, in 1965, 427 foreign physicians, of whom 86 were provided by WHO and 75 by Belgian and French assistance; the remainder worked primarily in mission hospitals and clinics or were under contract with the government.

To carry out a national programme with the situation as it was in 1967 represented a formidable undertaking.

### Smallpox Before 1967

During the decades preceding the beginning of the programme, several thousand cases of smallpox had been recorded annually in Zaire, but, because reporting was poor, this represented only a minute fraction of the total which had occurred. The disease was prevalent throughout the year, with no seasonal fluctuations. Mass vaccination campaigns had been conducted sporadically in urban areas and in some rural districts, but vaccination, employing locally produced liquid vaccine, was frequently unsuccessful.

It is probable that both variola major and variola minor prevailed in the country at different times. However, from 1962, smallpox with a case-fatality rate of 5–15%, similar to that in western Africa, was most widely prevalent. Official reports from Zaire usually distinguished between variola major and variola minor (Table 18.1). From these data, the inference might be drawn that variola major, similar in severity to that which occurred in Asia, coexisted with variola minor. During the course of the programme, however, it became apparent that health staff usually based their reports simply on the severity of the disease. Milder cases were customarily reported as variola minor and more severe cases as variola major.

Before 1962, overall case-fatality rates were below 5%, but subsequently they ranged from 5% to 15%. Since no changes are known to have occurred in reporting prac-

tices, it is presumed that a more serious form of the disease became more widespread about this time. After 1962 there were occasional undocumented anecdotal reports of outbreaks with few or no deaths; conversely, in Kinshasa a 1961–1962 epidemic was reported in which 280 (27%) of 1021 cases died. However, in the Kinshasa outbreak almost all the cases reported (of which 70% were in children under 5 years of age) were of the more severe type, requiring hospitalization.

Whatever the cause of the higher case-fatality rate, the government authorities of the newly independent country, as well as the foreign medical officers working there, were concerned about smallpox. In 1962–1963, they held meetings with the WHO medical officer for smallpox from Geneva to plan a pilot programme in one of the provinces. It was hoped that this would be followed by a national smallpox vaccination campaign. WHO was asked to provide medical officers, vehicles and equipment, but because of civil war, it was not possible to follow up the request. Meanwhile, smallpox vaccination throughout the country all but ceased. In 1965, WHO was again approached with a fully elaborated plan for a 4-year country-wide vaccination campaign, during which smallpox and BCG vaccines would be administered simultaneously. Such a programme had not been attempted before, in part because of the problems inherent in administering BCG vaccine.

Up to 1964, the administration of BCG

vaccine required that each potential vaccinee should be visited twice, with an interval of 2 days between visits. At the first visit, a non-infectious purified protein derivative (PPD) of the mycobacterium was injected intradermally, and 2 days later the site of injection was examined. The presence of a specified amount of induration at the test site indicated that the child had been infected with tuberculosis. Such children would not benefit from vaccination and thus were excluded from the group given BCG vaccine. The possibility of vaccinating all children, irrespective of whether or not they had had tuberculosis, had been considered, in order to eliminate the cumbersome and time-consuming process of prior testing with PPD. However, the occasional occurrence of unusually severe reactions to vaccine in the already infected group had contraindicated this approach. The WHO Expert Committee on Tuberculosis (1964) discussed the question at length and concluded that, as a practical matter, there was little choice in many countries but to eliminate testing with PPD on the premise that the overall benefits conferred by a logistically simplified BCG vaccination campaign outweighed the risk of a few serious reactions. This change in procedure made it more feasible to administer both vaccines at the same time. Moreover, because UNICEF was supporting many national BCG vaccination campaigns, but not those for smallpox, it was hoped that a combined campaign would elicit from UNICEF material assistance in the form of transport and equipment. The plan called for a national staff of 650, supported by 9 medical advisers, an operations officer, a statistician and an administrator made available by WHO. The magnitude of the programme and the proposed substantial commitment of government resources reflected a degree of interest in smallpox eradication in Zaire that was exceptional in African countries.

### **The Eradication Programme Begins, 1967-1968**

Because of the considerable United Nations and WHO commitment to Zaire, an office in WHO Headquarters rather than in the WHO Regional Office for Africa coordinated the Organization's activities in Zaire until 1968, dealing with such matters as the recruitment of staff and the procurement of supplies. In

November 1966, a medical officer from the Smallpox Eradication unit at Headquarters held discussions with national and WHO staff in Zaire and finalized a similar although somewhat more modest plan than that originally proposed by Zaire. Most of the support was to be provided by WHO, UNICEF agreeing to supply only the BCG vaccine, as well as the needles and syringes for its administration.

The overall operational strategy for vaccination was not dissimilar to that in other African countries. It called for 4 large vaccination groups, each composed of 6-8 teams. Each group would be directed by a WHO medical officer and, where available, a Zairian counterpart. Every team would have a supervisor; 3 pairs of vaccinators (a "vaccination unit"), one of each pair giving smallpox vaccine and one BCG vaccine; and a "control unit" of 3 vaccinators and a sanitary agent to visit a sample of the villages one week after vaccination to verify coverage and vaccination results. It was expected that each pair of vaccinators would be able to give 140 smallpox vaccinations and about 70 BCG vaccinations a day. Smallpox vaccination would be performed by scarification and BCG vaccination by intradermal inoculation using a syringe and needle. Village chiefs and local authorities would be notified in advance and asked to bring the people together at a convenient collecting point. In view of tribal and linguistic differences from area to area, local recruitment and the secondment of personnel from existing health services were anticipated.

The WHO senior medical officer was to be designated "co-director" of the programme rather than "adviser", in recognition of the more substantial role that the Organization was intended to play. In addition to the 4 medical officers who were to head the vaccination groups, WHO was also to provide an administrator, a public health nurse and a statistician—in all, 8 staff members, plus short-term consultants. The government complement was expected to amount to 363 persons, of whom 260 would be vaccinators. The cost to the government was set at US\$353 800 for the 1967 pilot project and at US\$677 000 annually for the principal "attack phase", which was scheduled to extend from 1968 to the end of 1970.

At the outset, WHO provided 34 Land Rovers with trailers, 6 trucks, 5 outboard motors, 14 motor cycles, 10 refrigerators plus

<sup>a</sup> Excluding the cost of 36 878 000 doses of vaccine.

camping gear, office equipment, megaphones and other miscellaneous supplies. WHO's support for this programme up to 1974 represented, on average, about 8.5% of all funds earmarked for smallpox eradication in the Organization's regular budget (Table 18.2).

Following completion of the mass vaccination campaign, it was expected that maintenance vaccination would be continued by the established health units, which by 1972 included 302 hospitals, 45 clinics, 2705 dispensaries and 242 maternity wards. Little attention was paid to reporting and surveillance in the 1966 plan of operations, reflecting the minimal interest in this component of the programme before 1967. As was stated in the plan: "Long-term objectives are to main-

tain smallpox eradication by appropriate surveillance methods as will emerge from experience and evaluation."

The post of WHO co-director was assigned to Dr Vladimir Zikmund, a WHO epidemiologist already working in Zaire; Dr Lekie Botee, a young Zairian medical officer, was appointed the national co-director—he was to serve in this role with great distinction throughout the early phases of the programme and later, to provide invaluable support as Director-General of Health Services.

The plan called for a pilot programme, to be initiated in 1967, in the course of which 2 groups would administer 2.86 million vaccinations; a full-scale programme, employing 4 operational groups, was scheduled to begin in 1968. Completion of the vaccination phase was foreseen by the end of 1970.

Because of difficulties in organizing so extensive a programme in a country only beginning to recover from civil war, progress was slow at first. Equipment began to arrive in July 1967 and most had been received by October. Two WHO medical officers, already assigned for work in Zaire, were transferred to the programme and a part-time finance officer was made available. At this point, efforts to recruit the remaining promised complement of WHO staff all but ceased. WHO's technical assistance programme in Zaire diminished significantly in scope as from 1967-1968, and responsibility for the Organiza-

**Plate 18.1.** A: Lekie Botee (b. 1930), the first Zairian co-director of the smallpox eradication programme in Zaire; when, later, he became Director-General of Health Services of Zaire he continued to play an active role in the programme. B: Pierre Ziegler (b. 1925), WHO co-director from 1968, was instrumental in redirecting operations and in establishing a management system.

tion's activities in Zaire was transferred to the Regional Office for Africa, which had only a small staff, a host of countries to serve and a staggering array of problems. Repeated pleas for additional staff were made but more than a year was to elapse before an administrative officer arrived; not until July 1971 was the promised complement of WHO staff made available.

Preparations for the field programmes were handicapped by the need for the medical officers to spend much of their time on administrative matters, including the creation of a central administrative office, the clearance of supplies through an inefficient customs office and their inventory and storage, and the shipment of vehicles and equipment to provincial capitals which were to serve as bases for field operations. Obtaining the release of government funds was yet another problem which persisted throughout the course of the programme, not infrequently requiring special intervention by the Minister of Health when depleted allocations threatened to stop activities. The part-time WHO finance officer, Mr S. O. Axell, wise in his knowledge of government, eventually obtained agreement to have the allotted funds deposited in a special bank account, and, in time, several such accounts were opened. When delays occurred in obtaining the funds allocated, especially at the beginning of a fiscal year, and the principal account was empty, reserves in the auxiliary accounts were used until the crisis could be resolved.

Because of the difficulties in getting the programme started, the pilot project in 1967 was limited to Kinshasa. It was not an auspicious beginning. The WHO co-director, seeking to ensure a thorough vaccination coverage, proposed that a census should be taken at the same time as the vaccinations were performed so that it could be known precisely what proportion of the population had been vaccinated. Thus, the vaccinators were instructed to prepare a separate card for each family, listing all members by name, age and sex and noting the date of vaccination. Later, an assessor visited each house, issued a special vaccination certificate to each individual successfully vaccinated and revaccinated those whose vaccination had not taken or who had been missed. The process was cumbersome and time-consuming. On average, the vaccinators performed only 20-30 vaccinations a day, and the Kinshasa programme concluded with only 220 000

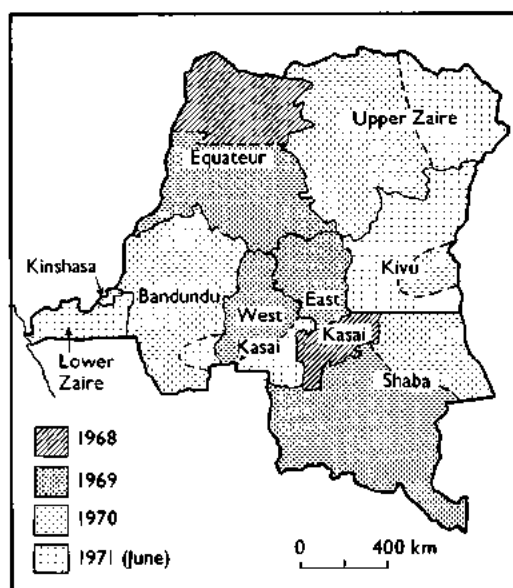

Fig. 18.2. Zaire: areas whose population was vaccinated in the systematic campaign, 1968-1971.

persons having been vaccinated in a target population of 1 million. Although the methodology was obviously faulty, no changes were made as the programme shifted from the pilot project stage to a mass vaccination campaign.

Three vaccination groups had been expected to begin work in 1968, but with only 2 WHO medical officers available to direct them, the programme was launched in only 2 provinces—East Kasai and Equateur (Fig. 18.2). In February, more vaccinators were recruited and trained and, in March, approximately 70 staff began work in East Kasai and 60 in Equateur. On 29 March 1968, a presidential decree gave the programme official status. For smallpox vaccination, most of the staff used the newly available bifurcated needles. In East Kasai, a number of jet injectors, such as were then in use in Brazil and western Africa, were supplied for large-scale vaccination at collecting points.

The jet injectors immediately proved to be widely favoured by the population and permitted the teams to vaccinate many more persons each day. However, the operational problems which characterized the pilot project worsened. The efficiency of the jet injectors was compromised by 3 facets of the programme: (1) the complex enumeration process; (2) the need to distribute vaccination certificates; and (3) the coordination of

smallpox vaccination with the time-consuming intradermal inoculation of BCG using a syringe and needle. Other methods were tried for enumerating the population. Special teams visited each area before vaccination and collected information by house-to-house visits or at collecting points. To simplify the process further, it was decided to record only the names of the heads of households, along with the number of household residents. In addition, efforts were made to persuade village leaders to provide this information. However, it was discovered that the number of people recorded as having been vaccinated in each village was greater than the total enumerated, the discrepancy being accounted for by an inadequate enumeration process and the fact that many individuals from outside the area attended the vaccination sessions. It became apparent that enumeration was a futile exercise. The name of the individual concerned had to be written on each vaccination certificate, after which it was stamped with an official stamp. For each jet injector in operation, on average 6 clerks were required to prepare the certificates. Lastly, the administration of BCG vaccine was an awkward procedure, often requiring, as one observer noted, 2 persons to hold the child and a third to inoculate.

The staffing patterns of the teams were changed to assign more persons to clerical work and to BCG vaccination, but progress remained discouragingly slow. By the end of September, smallpox vaccine had been given to 1 477 000 people and BCG vaccine to 644 000; at this rate the country-wide programme would have taken 8 years to complete.

#### **The Restructuring of the Programme, September 1968**

In September 1968, a new WHO co-director—Dr Pierre Ziegler—was appointed. Dr Ziegler had previously served for 16 years in Chad directing a mobile disease prevention and treatment service. During 1967, he worked there with United States Communicable Disease Center staff in the smallpox eradication-measles control programme and understood clearly the practicalities of executing a field programme. Dr Ziegler and Dr Lekie Botée decided to cease the enumeration activities. Instead, a sample survey of 5% of the villages was conducted after 6–8 days to

assess the take rates of smallpox vaccination, and again after 2–3 months to assess the take rates of BCG vaccine and overall vaccination coverage. The problem of vaccination certificates proved to be more difficult to deal with because the government insisted on their use and the population was accustomed to receiving them. Procedures for their issuance, however, were greatly facilitated by requiring a member of the team to stamp the certificates and by asking the vaccinee to enter his or her name on the document. Finally, the teams began to use the jet injectors to administer BCG vaccine as well, a recently (albeit incompletely) evaluated technique of BCG vaccination. WHO regional personnel and national tuberculosis advisory staff, in deference to tradition, objected to the adoption of this practice, but eventually acquiesced when Dr Halfdan Mahler, then Chief of the WHO Tuberculosis unit, endorsed it and ordered all to cooperate.

Each vaccination group was reorganized to consist of 5 teams, each with a Land Rover and 5 jet injectors. Every team had 6 members—the team leader, 1 vaccinator for smallpox vaccine and 1 for BCG vaccine, a person to stamp and distribute certificates, another to tally the vaccinees and reconstitute the vaccine, and a driver. One additional team worked with each group to contact the chiefs of all villages 1 or 2 days before the vaccination teams arrived, to explain the programme and to obtain the cooperation of village leaders. An assessment team made up the rest of the field staff.

Each operational group maintained a headquarters in the capital city of the province in which it was working and temporary field camps as it moved through the province. In addition to the field teams, each group had a small administrative unit—a total complement of about 50 persons. Each group was equipped with 10 Land Rovers, 2 trucks, 30 jet injectors and several refrigerators. Each team had specific daily and monthly targets, but was allowed a certain flexibility in its schedule to accommodate the need for frequent long trips by boat and on foot.

The pace of activity began to increase. During the last 3 months of 1968, as many people were vaccinated as during the first 6 months of the programme. By the end of the year, 2 275 000 smallpox vaccinations had been performed over a broad area stretching across the central part of the country. Here, assessment revealed that, except in the most

### A Problem Bred by Efficiency

The vaccine standards called for the freeze-dried smallpox vaccine to retain its potency for 30 days when incubated at 37 °C. Thus, in all programmes, provision was made to refrigerate the vaccine at 4 °C at central storage depots and at distribution points in the field to ensure, as far as possible, that vaccine reaching the vaccinee was fully potent. The diluent for the vaccine, however, did not need to be refrigerated. Much of the vaccine provided to WHO came from the USSR, which, like most vaccine manufacturers, packaged both vaccine and diluent in the same box. With this manner of packaging, much more refrigerated storage space was required than if the diluent and vaccine had been packaged separately. Because refrigerated storage facilities were at a premium in all countries, WHO approached the Soviet authorities and proposed that the two should be separately packaged and this was agreed. In 1970, vaccine and diluent began to be distributed in separate boxes, which were clearly marked and had labels of different colours so that there would be no confusion.

Regrettably, the change in the manner of packaging was not at first noted in Zaire until a vaccination team, after 3 weeks' journey into the forest, opened the boxes to begin a vaccination campaign—only to find that they had brought with them nothing but diluent.

isolated districts, more than 90% of the population were being vaccinated. On average, each team was able to administer daily 1200 smallpox vaccinations and 600 BCG vaccinations. In only a few months, Dr Ziegler and Dr Lekie Botee, assisted by 2 WHO group leaders, Dr P. Cartagena and Dr E. Zanotto, had transformed a chaotic operation into a remarkably efficient machine.

In January 1969, the programme began to publish a monthly surveillance bulletin, which was distributed to 943 health units throughout the country. It documented the numbers of cases reported from each province and the progress of the campaign, exhorted all to report cases of smallpox, and urged health units to undertake vaccination.

Until 1969, few of the personnel in the extensive network of health centres, clinics and hospitals had administered vaccines of any type. Those who had done so had been supplied with either liquid smallpox vaccine or a substandard freeze-dried product produced by a laboratory in Lubumbashi. A WHO consultant was recruited to determine whether, with assistance, the laboratory could produce satisfactory vaccine, but the problems were too numerous and the laboratory was closed. In June 1969, it was agreed that only vaccine that met WHO requirements would be used, and thereafter vaccine supplied by WHO, emanating principally from the USSR, replaced the local product. With the continuing encouragement of the small-

pox eradication programme staff, the numbers of smallpox vaccinations performed in health centres and clinics increased from 575 000 in 1968 to 3 575 000 in 1969, although some health centre staff, preoccupied with curative medicine, refused to participate in the campaign.

In February 1969, Mr A. Samy, an administrator, was recruited by WHO. A resourceful and experienced person, he soon established a sophisticated vehicle repair and maintenance workshop—a necessity because, as noted in a report: "Despite more than 3000 Land Rovers in service in the country, the after-sales service provided is inadequate as for repair and often nonexistent concerning locally available spare parts." Records of repair and maintenance schedules were established for all vehicles, mechanics were recruited and trained, and trailers were rebuilt to permit them to carry petrol, often unavailable in remote parts of Zaire. A workshop for repair of the jet injectors was also established, along with an inventory of spare parts.

The logistic and operational problems were formidable but programme staff, with ingenuity and persistence, competently dealt with them. The recruitment of the required WHO staff, the placement of orders for equipment and the arrangements for its shipment were, however, beyond their control, these tasks being the responsibility of the WHO regional office. All were greatly delayed. Even the use of BCG vaccine had to be

**Plate 18.2.** A: The protracted fighting in Zaire devastated the road system, and vehicles frequently became mired along bush trails. B: Broken chassis were common; without a special repair and maintenance workshop, the programme would have foundered.

interrupted for a period when UNICEF decided to send the vaccine by air but the diluent for reconstituting it by sea. The only supplies which did not present a problem were smallpox vaccine, bifurcated needles and jet injectors. These could be provided promptly, on request, from a reserve stockpile held at WHO Headquarters.

In January 1969, Dr Ziegler and Dr Lekie Botee decided—and the government supported them with an appropriate request to the regional office—that persons with qualifications similar to those of staff employed by the United States Communicable Disease Center in western Africa should be recruited as WHO operations officers. It was expected that they would organize provincial surveillance teams so as to strengthen reporting and investigate outbreaks. WHO agreed to recruit 5 such persons, but more than 2 years were to elapse before 4 of the 5 arrived. Meanwhile, with only 2 WHO medical officers available for field work and no Zairian staff who could independently supervise field activities, Dr Ziegler and Dr Lekie Botee had no option but to pursue the vaccination campaign, postponing surveillance until adequate staff became available.

The vaccination campaign steadily gained momentum: between April and June 1969 an average of about 500 000 smallpox vaccinations were administered each month, com-

pared with only 200 000 a month the year before. In July, a third vaccination group was able to begin work under the supervision of a WHO medical officer recruited from among the foreign medical staff remaining in Zaire. He was replaced later that year by the first of the WHO operations officers, Mr Garry Presthus, who was to provide able assistance first in Zaire and later in Botswana. By the end of 1969, more than 8 million persons had received smallpox vaccine and almost 3.5 million BCG vaccine (Fig. 18.3). The total was less than the optimistic target projected in 1966, but the gap was narrowing. The results of continuing assessment showed a vacci-

nation coverage which frequently exceeded 95% and was never below 80%.

The number of recorded cases decreased from 3800 in 1968 to 2072 in 1969 (Table 18.3; Fig. 18.4), a significant reduction in view of the fact that more medical units, encouraged through the monthly surveillance bulletin, began to report each week the number of cases of smallpox seen. During 1969, an average of 87 medical units out of an estimated 535 provided weekly reports—a far from optimum response but an improvement over 1968. The highest proportion of reports was received from the provinces in which the vaccination groups had worked and the medical units had been most thoroughly briefed about the programme. In East Kasai Province, in which the vaccination campaign was completed in February 1969, the results were dramatic (Fig. 18.5).

#### The Vaccination Campaign Becomes Fully Established, 1970

Most of the supplies and equipment had been received by 1969 (Table 18.4), sufficient to meet the needs of 4 vaccination groups, but it was not possible to establish a fourth group

Fig. 18.4. Zaire: number of reported cases of smallpox, by month, 1968–1971.

until February 1970, when Dr Ziegler succeeded in arranging for the transfer of another locally employed foreign medical officer, Dr A. Hornbanger. In just 8 weeks Dr Hornbanger's group of 7 teams, based in Kinshasa, performed more than 1.6 million smallpox vaccinations and 800 000 BCG vaccinations in the city; during March, each team of 6 persons gave, on average, 5300 smallpox vaccinations and 2800 BCG vaccinations a day.

With 4 groups in the field, the complement of national personnel increased until it reached its highest number—234 persons—a ratio of 1 staff member for about 100 000 inhabitants (Table 18.5). There were 9 international staff. The vaccination campaign progressed rapidly despite the fact that groups were beginning to spend more time in the least accessible regions of the country, where travel by boat and on foot was frequently required. For example, one group, consisting of 50 persons, which had succeeded in vaccinating 915 000 people in one month in an accessible, more populated, area, was able to

vaccinate only 54 000 people during the succeeding month.

By the end of 1970, 17 million persons had been vaccinated against smallpox and systematic programmes had been completed throughout the country except in areas in which security had been a problem, and in Lower Zaire, near Kinshasa, in which few cases were being detected and which, accordingly, had lower priority.

### The Problem of Surveillance

Dr Ziegler and Dr Lekie Bottee continued to worry about reporting and surveillance. The recruitment of operations officers who could lead surveillance–containment teams had been expected but the arrival of only one such officer, late in 1969, was of little help. The creation of a national team was considered but, in a country so large and with travel so difficult, it was decided that this would be unproductive. Moreover, communications were a major problem, so that even when cases were discovered notification was so greatly delayed that it was difficult for a single team to be effective. For example, a telegraphic message sent in April, reporting cases in a province adjacent to Kinshasa, took a month to reach Kinshasa.

Each of the health units throughout the country continued to be encouraged to vaccinate, to report cases and to contain outbreaks. Although the average number of reports received each week increased from 87 in 1969

<sup>a</sup> Two cases of chickenpox incorrectly notified as smallpox.

to 140 in 1970, there were still many units which did not report at all.

During 1970, only 716 cases were reported, the lowest total recorded in Zaire since a national reporting system had been introduced. By September, fewer than 50 cases a month were being discovered, most of them in eastern Kivu Province (Table 18.6), in which the vaccination campaign was still in progress. At least some of the reported cases were thought to be chickenpox, since they were noted as having occurred in young children with a distinctive vaccination scar. In the hope of getting a more accurate assessment of this problem, Dr Ziegler and Dr Lekie Botee decided to distribute collection kits and to ask those who reported cases to submit specimens for examination by WHO reference laboratories. However, the distribution of the kits, as well as their return, proved troublesome because of the poor postal service.

Frustrated by WHO's inaction in recruiting staff, Dr Lekie Botee and Dr Ziegler in Kinshasa and Henderson, on a special trip to Washington, approached the United States government, requesting the assignment of 8 Peace Corps volunteers from the USA. This had to be done unofficially, because at that time it was the policy of WHO that the assignment of national volunteers should be decided on and worked out by agreement between the national governments concerned. WHO staff were to play no role in encouraging their assignment in any country or in supporting their activities. However, the Zaire programme was desperate for personnel to undertake surveillance activities and there appeared to be no other alternative. United States officials were themselves not initially enthusiastic about the proposal because of their policy of assigning Peace Corps volun-

teers to specific areas in which they would become acquainted with the local people during their tour of duty. The surveillance teams, in contrast, were expected to travel constantly over an extensive area. Moreover, the task of supervising a surveillance team was felt to be unusually demanding. Reluctantly, the USA agreed to select Peace Corps volunteers who had performed especially well during a 2-year assignment and wished to extend their tour of duty for a year or more. Those appointed were to prove invaluable.

### The Discovery of a Case of Monkeypox in a Human Being

The imperative need for surveillance was heightened by the identification in October 1970 of the first recognized case of monkeypox in a human being. The WHO reference laboratory in Moscow isolated monkeypox virus from a specimen collected from a child who had become ill on 22 August 1970. The virus had been isolated previously from outbreaks of disease in captive monkeys but never before from a human (see Chapter 29). Nothing was known about the possible clinical manifestations in humans or about the potentialities for spread from human to human. Recalling that yellow fever eradication had been thwarted in the 1930s when a natural reservoir in mammals had been discovered, WHO staff were deeply concerned that monkeypox virus might be analogous to sylvan yellow fever virus, perhaps dooming the objective of global eradication. Concern grew when, within a week, 4 cases in Liberia were confirmed as monkeypox by the WHO reference laboratory in Atlanta, USA.

Ladnyi, at that time the WHO inter-country smallpox adviser in eastern and

M.V. SZCZENIOWSKI, 1984

southern Africa, joined Dr Ziegler early in January 1971 to investigate the case in Zaïre. The child, a 9-month-old boy, had been admitted on 1 September to a hospital in Basankusu, a small town in the central part of Equateur Province. He had a rash with a distribution like that of smallpox but because the lesions were haemorrhagic, the physician was uncertain of the diagnosis and had taken a specimen. After admission the child developed enlarged cervical glands as well as otitis and mastoiditis. Subsequently, he contracted measles and died on 29 October. Ladnyi and Dr Ziegler searched for other cases with rash in Basankusu town and in the village in which the child had lived until 4 days before becoming ill. No cases could be found, although it was ascertained that the family of the patient occasionally ate monkeys, as did many other people in the area.

The nature of the area and the difficulties of travel and communication in this and many other parts of Zaïre is conveyed in the report of Ladnyi and Dr Ziegler. Equateur Province was made up of 4 districts, each district consisting of a number of territories, of which Basankusu Territory was one. To travel from Kinshasa to Mbandaka, the provincial capital, and from there to Basankusu town was difficult. A weekly air flight, often cancelled,

connected Kinshasa with the two towns. Travel by road meant crossing no fewer than 20 lakes and rivers, only some of which had a regular ferry service. Twice monthly, a riverboat made a 2-day trip to Mbandaka, where, after a wait of several days, one could transfer to another boat for a further 2-day trip to Basankusu. A cable to Kinshasa often took a month or longer to deliver. Basankusu Territory covered an area of 20 000 square kilometres and had a population of 62 000, mainly primitive farmers living in small villages scattered along paths and tracks in dense tropical rain forest. The distance from the capital of the territory to the most remote villages was 150 kilometres. Only one all-weather road crossed the territory, intersected by several impassable rivers with neither bridges nor regular ferry services. Travel along the tracks and paths was difficult, the so-called rainy season being 10 months long; even in the drier months, rain fell 2 or 3 days a week.

Basankusu Territory was served by a government hospital and 18 dispensaries scattered throughout the area, some operated by government health staff and some by missionaries. Smallpox had been present in the district in 1968 but no cases were known to have occurred in 1969. Two cases had been reported in 1970, one of which was discovered to have been chickenpox; the other was the case of monkeypox.

Vaccination had been performed by the teams in 1969, but no special containment vaccination programme had been conducted after discovery of the monkeypox case. Ladnyi and Dr Ziegler carried out a vaccination scar survey in 6 villages near where the patient lived, 115 kilometres from Basankusu town. The results are indicative of the thoroughness of the vaccination campaign (Table 18.7).

Twenty-one persons had characteristic residual pockmarks of smallpox but their illnesses had all occurred before or during 1968,

**Table 18.7.** Basankusu Territory: results of vaccination scar survey, by age group, 1970

Age group (years)	Number assessed	Subjects with vaccination scars	
		Number	%

Total	1 132	1 065	94.1

when smallpox had been widely prevalent. In this instance, at least, monkeypox appeared not to have spread to other human beings. The results of this and subsequent investigations of cases of monkeypox are described in Chapter 29. Eventually the studies confirmed that cases of monkeypox in humans were rare and that the disease spread only with difficulty from human to human.

### **The Creation of a Surveillance Programme, 1971**

In January 1971, 5 provincial surveillance teams were established with the eventual arrival of 2 additional WHO operations officers and 3 United States Peace Corps volunteers. One of the 2 operations officers, Mr Mark Szczeniowski, was to remain with the programme in Zaire over the following 15 years, continuing the programme of surveillance and supervising special investigations of monkeypox. Each of the teams had a vehicle, a driver, a Zairian counterpart and a vaccinator. Each was equipped with a 100-watt transceiver in order to communicate rapidly with Kinshasa, with their provincial base of opera-

tions, and with each other. In their respective areas, they began to visit in a systematic fashion all hospitals, dispensaries and health centres to inquire about possible cases, to request immediate notification of any suspected case, to distribute vaccine and needles and to encourage each establishment to vaccinate everyone who attended it. Each health facility was visited once or twice every 6 months. The teams investigated all suspected cases and obtained specimens. In addition, in different villages they undertook a random scar survey assessment of about 2000 persons each month to assess the status of vaccinal immunity. Each team spent 21 days in constant travel, followed by a week's holiday.

By July 1971, 11 surveillance teams were in operation; 2 were assigned to each of the 3 largest provinces, and 1 each to the smaller ones. With the termination of the vaccination campaign at the end of July, the numbers of national staff were reduced and the medical officers who had served as group leaders each assumed supervisory responsibility for several provinces.

During the vaccination campaign, more than 24.3 million persons were vaccinated against smallpox and 11.4 million received

J. G. BREMAN

**Plate 18.4.** The surveillance programme in Zaire began in January 1971 and continued into the 1980s as teams sought human cases of monkeypox, a disease clinically almost identical to smallpox. Schoolchildren were shown pictures of smallpox in the WHO pictorial guides and asked if they had seen any cases.

<sup>a</sup> Derived from United Nations (1985).

BCG vaccine (Table 18.8). All parts of the country had been reached except for a small area in Kivu Province with a population of 115 000 persons. Even there, where security remained a problem, the staff were able to vaccinate some 50 000 people, although not in the systematic manner in which the rest of the campaign had been conducted.

The number of cases diminished rapidly during 1971. No cases were discovered in July and only 2 in August—the last reported cases in Zaire. The occurrence of these 2 cases, in West Kasai Province, long after any previous notifications there, was most puzzling. Extensive investigation, however, revealed that they were cases of chickenpox. Thus, a case in June in Upper Zaire appears to have been the last in the country, occurring just as the vaccination campaign concluded.

By the time this last case had occurred, Zaire's only infected neighbour was the Sudan, in which cases continued to occur in border areas until December 1972. No importations were detected in Zaire, despite continuing, intensive search by a specially assigned surveillance team headed by one of the WHO medical officers.

Data regarding the age and vaccination status are available for 2124 cases that occurred between 1969 and 1971 (Table 18.9).

The surveillance teams, with a staff of 95, continued to function until eradication was certified in Zaire in 1977, although international staff were gradually replaced by experienced Zairian counterparts. A special programme for the surveillance and investigation of monkeypox continued through 1986 (see Chapter 29).

Between 1971 and July 1976, nearly 700 specimens were collected, of which 3 (in

1971) contained variola virus, 9 contained monkeypox virus, 88 contained viruses of the herpes-varicella group and 6 contained either vaccinia virus or tanapox virus (Table 18.10).

Eventually, the teams were successful in obtaining the cooperation of all but a few of the 3289 health establishments in performing vaccinations. A surprisingly large number of vaccinations were given (Table 18.11), especially after the surveillance teams began their regular schedule of visits in 1971.

As Dr Ziegler was to observe, many staff working in rural dispensaries had not been

**Plate 18.5. visited by a physician or nurse for 10 years or more. They responded enthusiastically to the visits of the surveillance teams and many conscientiously undertook to sustain high levels of vaccinia immunity, not only among the people coming to their dispensaries but among the inhabitants of nearby villages as well. The results as measured by scar surveys in 1972 and again in 1974 confirm the success of this effort (Table 18.12).

Eventually 238 reporting sites were identified and charged with the responsibility of reporting weekly any suspected cases of smallpox and chickenpox. This network, which included 92 hospitals, 39 health centres, 54 dispensaries and 48 district or provincial health and medical units, ultimately served as a national morbidity reporting system. The response was remarkably good considering the difficulties of communication (Table 18.13).

During the surveillance period, the mobile teams with their transceivers provided a mechanism for the emergency reporting of outbreaks of other diseases, such as plague, yellow fever and cerebrospinal meningitis. Often the teams themselves participated in special programmes to control these outbreaks.

## SUDAN

### Background

The Sudan, even larger in area than Zaire, was no less important geographically to the strategy of the eradication programme—but for different reasons. Following a mass vaccination campaign conducted during 1961–1963, the Sudan became free of smallpox and is believed to have remained non-endemic until 1968. However, the risk of the disease being imported into the country and becoming re-established was high. Traditional caravan routes between Mecca and the endemic countries of western Africa crossed the north-central area of the Sudan and, historically, many outbreaks had been traced to cases imported by such travellers. To the east lay heavily endemic Ethiopia, whence came some 200 000 seasonal labourers each year for the harvesting of *dura* (sorghum). In addition, because of civil war in northern Ethiopia, thousands of refugees from Eritrea had moved across the Sudan's north-eastern borders, many of them returning periodically to Ethiopia. In the southern part of the Sudan, a civil war had been in progress since 1956 and many refugees frequently travelled between the Sudan and camps in Uganda and Zaire.

In 1967, the Sudan expressed interest in participating in the smallpox eradication programme, the principal component of which would be a campaign during which, as in Zaire, BCG vaccine would be administered at the same time as smallpox vaccine. The programme, however, did not begin until 1969 and proceeded slowly thereafter, the logistics of administering the two vaccines at the same time never being satisfactorily worked out.

Meanwhile, 9 cases of smallpox thought to be importations occurred in 1967, and during the first few months of 1968, 104 cases were detected. Investigation suggested that they were attributable to an importation from Ethiopia. No cases were discovered after June and it was thought that the outbreak had been satisfactorily contained. However, cases were again detected in December 1968 and in the early months of 1969 in many of the same areas. Once more, special investigations were undertaken. In all, 119 cases were documented but it was believed that there were many others which had not been detected. Although the initial outbreaks had occurred near the Ethiopian border, it was clear that

many had originated in rural areas of the southern Sudan, unreachable because of civil war. It was suspected that endemic smallpox had become re-established and, in 1970, this became a certainty as the disease spread widely across the country.

Repeated attempts had been made to persuade WHO advisers and senior Sudanese staff that a continuing programme of surveillance and containment was vitally important in a country which was thought to be smallpox-free, but little was done until 1972. A seminar held in December 1971 marked a turning-point. A Sudanese medical officer, Dr Omer Sulieman, rapidly organized a surveillance-containment programme in the north, beginning in January 1972. In April, he moved to the south on conclusion of the civil war. Working with extraordinary energy and skill, he and Sudanese programme staff stopped transmission in December 1972. Subsequently, programme staff conducted a thorough search and vaccination campaign over extensive areas along the Ethiopian border in collaboration with Ethiopian staff, and at times assisted the programme in Ethiopia through search and case investigation far inside the frontiers of that country.

There was some speculation that the Sudan had never been smallpox-free, that transmission had always continued in inaccessible areas of the war-torn southern provinces. In retrospect, however, the epidemiological data strongly support the belief that transmission in the Sudan was interrupted in 1962 and endemic smallpox did not recur until after the importations of 1967–1968.

### Population Movements

The Sudan is diverse in character, with extensive desert throughout the north giving way to steppe and grassland in the central part of the country and to large marshes and tropical forest areas in the south-eastern and southern parts of the country. The White Nile extends the length of the country, some 2000 kilometres, providing river transport and irrigation in the east central region. It is joined at Khartoum, the capital, by the Blue Nile, which flows from Ethiopia. Nearly half of the Sudan's 12.9 million population (in 1967) live in the fertile, extensively irrigated areas of Khartoum, Kordofan and Blue Nile Provinces near the confluence of the two rivers (Fig. 18.6).

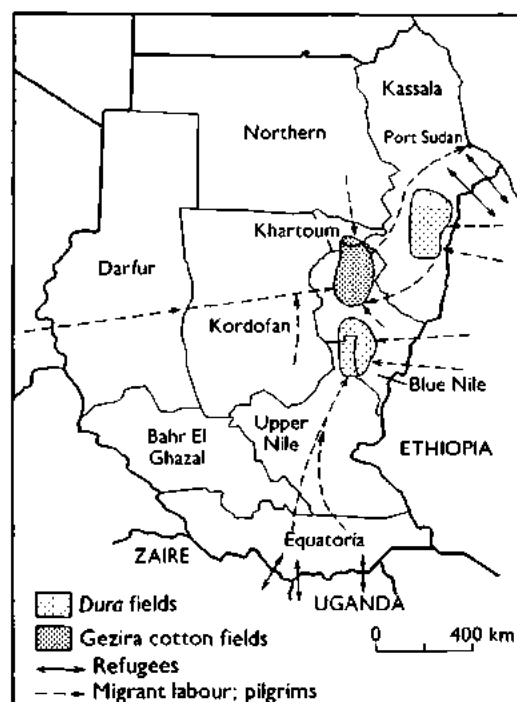

Fig. 18.6 Sudan: movement of refugees and seasonal populations.

The seasonal migration of agricultural workers was a significant factor in the spread of smallpox within the country and in the importation of the disease from Ethiopia. South of Khartoum were the great cotton fields of the Gezira Irrigation Scheme, which employed some 350 000 workers between mid-December and May. The labour force consisted largely of Sudanese workers recruited in various provinces and transported in large groups to and from the area by truck and boat. As important were the *dura* fields in Kassala, Blue Nile and Upper Nile Provinces, which attracted some 400 000 seasonal labourers, most of whom were employed for the harvest during December–February. Half of the workers came from Ethiopia, many of them travelling on foot for as long as 2–3 weeks to reach the area.

Other factors contributed to the movement of population and the spread of smallpox. Some 1.5 million pastoral nomads roamed the central and northern regions of the Sudan. In the north-east, upwards of 100 000 Ethiopian refugees from Eritrea camped near border areas but moved in and out of the country. Additionally, each year 30 000–40 000 pilgrims to Mecca from western Africa travelled

across the country, through Khartoum. Population movements, overall, were far more extensive than in other Saharan and sub-Saharan African countries.

Civil war in the 3 southernmost provinces, which began at the time of independence in 1956, when tribal populations revolted against traditional leadership, was another serious problem. An estimated 50 000–100 000 Sudanese refugees from Equatoria Province lived in northern Uganda and Zaire but regularly moved in and out of the Sudan. Until March 1972, when a peace treaty was signed, much of the rural area in these southern provinces could be penetrated only by military convoy; health activities, including smallpox vaccination, were few; roads and bridges were destroyed or deteriorated.

Health facilities were reasonably numerous in the Sudan, although in a country so large they were widely dispersed. A tabulation drawn up in 1976 listed 127 hospitals, 159 health centres, 590 dispensaries and 1214 dressing stations.

### Smallpox in the Sudan before 1968

Records of cases of and deaths from smallpox have been available since 1925. Up to the end of 1958, these show case-fatality rates in most years of 10–20%, with between 12 and almost 6500 cases reported each year. Major outbreaks occurred sporadically, the last being recorded during the period 1952–1955 in Darfur Province and the 3 southern provinces. Mass vaccination campaigns were conducted whenever outbreaks developed. Each year, 500 000–2 000 000 persons were vaccinated with liquid vaccine produced at a laboratory in Khartoum. Routine vaccination was rarely performed by the health units but enough persons were being vaccinated in mass campaigns to discourage the practice of variolation, which had once been widely prevalent.

In 1959 case-fatality rates abruptly declined (Table 18.14), falling to levels typical of those of *variola minor*. Since most of the cases during that year and the 3 subsequent years were recorded in Blue Nile Province, adjacent to Ethiopia, it is probable that the virus strain originated in that country.

Following the decision of the Twelfth World Health Assembly, in May 1959, to carry out global smallpox eradication, the Sudanese government requested assistance

from WHO to undertake a national vaccination campaign. WHO provided US\$12 000 for vehicles and refrigerators and the USSR contributed freeze-dried vaccine. Except for this support, the programme was entirely a national effort, utilizing temporary staff who vaccinated by house-to-house visits and, in some areas, at collecting points. The transport provided by WHO was supplemented by rented vehicles and some provided by the military. During a 3-year period (1962-1964) 8 840 152 vaccinations were performed, a number equivalent to about 75% of the total population. The central and northern provinces were much better vaccinated than the 3

war-ridden southern provinces: in Upper Nile and Bar el Ghazal Provinces the coverage was very limited and in Equatoria Province it was nonexistent.

Although many persons remained unvaccinated, the campaign was successful in controlling smallpox. Except for an outbreak of 69 cases in Darfur Province in 1965 and 9 cases in 1967, no cases were reported in the Sudan during the years 1963-1967. Following the mass campaign, the numbers of vaccinations again fell off, averaging just 500 000 per year from 1964 to 1967, and because liquid vaccine was again employed, it is probable that only a small proportion were successful.

### The Decision to Undertake an Eradication Programme, 1967

Because so few people were vaccinated after 1964, it was assumed in 1967 that few of those under the age of 5 years had ever been successfully vaccinated and that large numbers throughout rural areas of the southern provinces remained susceptible. No cases were being detected by staff of the comparatively extensive infrastructure of health services but concern was expressed that smallpox, if imported, might recur in epidemic form. Accordingly, it was decided in June 1967 to undertake another 3-year national vaccination campaign, and Dr Abdel Hamid El Sayed Osman was placed in charge. The inhabitants of provinces in the central region (Table 18.15) would be vaccinated first, followed in the second year by those of the

<sup>b</sup> Excluding the cost of 16 635 000 doses of vaccine.

provinces in the northern region. By that time it was hoped that the civil war in the southern provinces would have ceased, permitting operations to be conducted there. This initial vaccination of the population of the central provinces could help to ensure high levels of immunity in the agricultural areas, which received large numbers of migrant labourers, and thus serve to prevent the possible spread of smallpox to the northern provinces. However, little attention was given to the development of a reporting system or of a mechanism for the investigation of suspected cases.

WHO support was greater than during the earlier campaigns (Table 18.16) and this time included the services of a WHO adviser. Commitments of the Sudanese government were substantial and included a staff of 539 persons.

It was expected that transport and supplies would arrive in the autumn of 1967, thus permitting the programme to begin towards the end of the year. In 1967, however, war between Egypt and Israel closed the Suez Canal, and supplies and equipment had to be rerouted around the Cape of Good Hope. What with the longer journey and the chaos in shipping, the supplies did not arrive until early 1969. Meanwhile, freeze-dried vaccine was supplied by WHO for use by health service units. However, as in other countries, very few vaccinations were performed.

### Smallpox is Reintroduced into the Sudan

The first of what were thought to be imported outbreaks occurred in Khartoum in

July 1967, when 4 cases of smallpox were discovered whose source of infection was not identified. Because of the outbreak, a mass vaccination campaign was conducted in and near the city over a 3-week period, during which 717 904 persons were vaccinated. As expected, it was found that few children under 5 years (17%) had been vaccinated previously. In December, another outbreak of 5 cases occurred in Khartoum among Ethiopians from Eritrea, but smallpox did not spread among the now well-vaccinated population.

Beginning in February 1968, more outbreaks began to occur but little is known about their source or true magnitude. The importance of surveillance and containment measures was not then appreciated in the Sudan. In February, a patient from Kordofan Province developed smallpox in Khartoum, the probable source being vaguely identified as a market in Darfur Province. Smallpox was not known to be present in Darfur but no investigation was conducted. However, a mass vaccination campaign was organized in Kordofan during which 801 778 persons were vaccinated. In March, another case was recorded in Khartoum but its origins were not investigated.

WHO staff both in Geneva and in the Regional Office for the Eastern Mediterranean were alarmed by the occurrence of smallpox in a country which was thought to be free of the disease and anxiously sought additional information from the government and from the WHO smallpox adviser assigned to the Sudanese programme, but to no avail. In April 1968, cases began to be reported in Upper Nile Province as well. Dr Ehsan Shafa, the WHO Regional Adviser on Smallpox Eradication, was concerned about the situation and spent 2 months investigating outbreaks in this area and organizing mass vaccination campaigns. The first case was thought to have developed in December 1967, shortly after the infected person had arrived from Ethiopia. From there smallpox appeared to have spread to 10 other localities in Upper Nile Province. Subsequently, cases occurred in 3 areas which were 600 kilometres to the north, 1 area in Kassala Province and 2 in Blue Nile Province (Fig. 18.7), but their sources of infection were not identified. In all, 76 cases were detected in Upper Nile Province, the last on 16 May 1968. The discovery that the first known outbreak originated in Ethiopia, and that other outbreaks followed

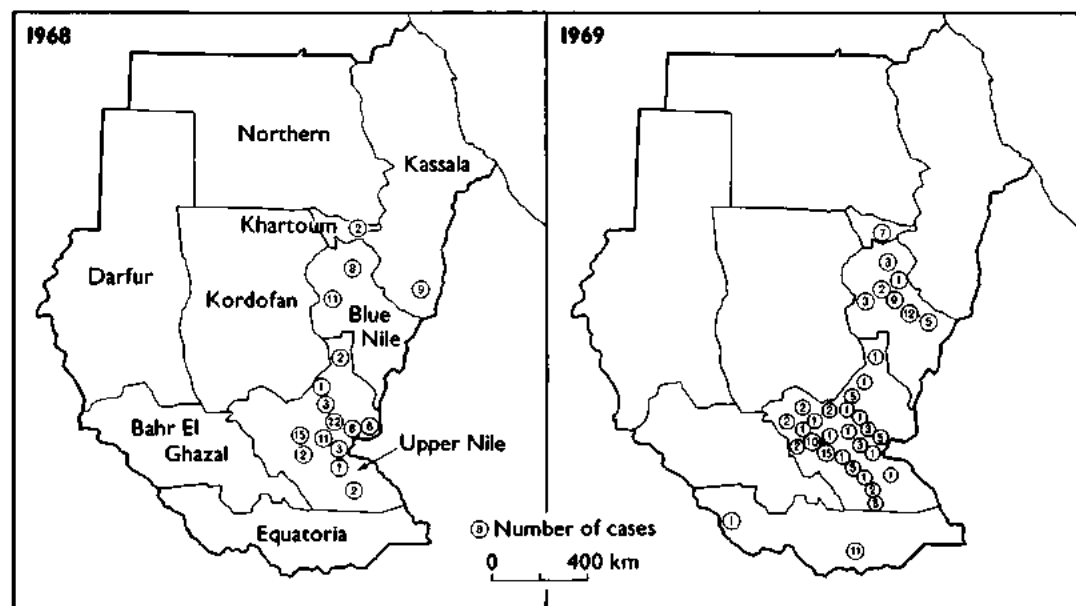

Fig. 18.7. Sudan: geographical distribution of reported cases of smallpox, 1968–1969.

in a temporal sequence moving from south to north, suggested that the series of outbreaks had originated from an importation with subsequent spread in a country otherwise free of smallpox.

To control the early 1968 outbreaks, mass vaccination campaigns were conducted in April and May: 452 256 persons were vaccinated in a single month in Upper Nile Province, 23 005 in Kassala Province, and 638 015 in Blue Nile Province—in all, more than a million people. Few vaccinations had been performed in Upper Nile Province during the 1961–1963 campaign, and the 1968 campaign reflected this. Of those aged 1–4 years, 72% received primary vaccination, as did 61% of the whole population. Primary vaccinees accounted for only 24% of the total in Kassala Province and for only 18% in Blue Nile Province. The last cases in these outbreaks were detected in June. Over the next 5 months, no further cases were reported (see Fig. 18.8).

#### The National Mass Vaccination Campaign is Launched, 1969

Considering the size of the country and the extensive movement of population in the Sudan, it was recognized that an effective

mass vaccination campaign would be a challenge. Favouring its success, however, was the fact that the country's infrastructure of health services was among the best developed in Africa; maps and demographic data were available for most districts and council areas; and health units were widely dispersed. Moreover, a national vaccination campaign had been completed less than 5 years earlier. However, from its inception, the campaign experienced an array of problems. In mid-1968, 190 vaccinators were appointed, trained and posted to the central provinces. Within a short period, most resigned and returned to Khartoum, having found it difficult to cope with field conditions and having encountered resentment by the villagers, who were accustomed to locally recruited vaccinators. New staff were recruited and trained, of whom a greater proportion were from the provinces to be vaccinated, and in January 1969 field operations began.

The staff of 539 was substantially greater, in proportion to population, than in other African countries, in part because of the government's decision to provide BCG vaccine at the same time as the smallpox vaccine. Superficially, this appeared logical, but in practice it presented special problems. Smallpox vaccination in the Sudan was customarily performed by vaccinators proceeding from

house to house, the assembly of large numbers of people at collecting points not being well accepted in most areas. Because of this, jet injectors were not useful. Although smallpox vaccination, administered with the bifurcated needle, was well suited to house-to-house vaccination, BCG vaccination, which required the use of a needle and syringe, was not. Among the problems was that the needles had to be flamed after each inoculation and the syringes repeatedly refilled from the vaccine vial. Accordingly, BCG vaccine was customarily administered at assembly points. To the smallpox staff, it appeared impracticable to try to combine a house-to-house vaccination campaign with one which called for the gathering of children at a collecting point, but the government, supported by the WHO Regional Adviser for Tuberculosis, decided on the combined programme. Unfortunately, the operational problems were never resolved.

For the campaign, 30 vaccination units were constituted, approximately 10 for each of 3 provinces (Blue Nile, Darfur and Kordofan), each unit comprising 6 smallpox and 3 BCG vaccinators plus supervisors. The units moved systematically through the province. The smallpox vaccinators went from house to house; the BCG vaccinators worked at a collecting point, vaccinating those up to 20 years of age. Each group prepared a separate set of records listing the name of the head of each household, the number of residents by age group and the number of vaccinations performed. Thus, two sets of forms were prepared in each village; no effort was made to reconcile them and, in fact, the records were not subsequently used either in assessment or in follow-up vaccination.

The plan for assessment of vaccination coverage and take rates was likewise inefficient. It called for a separate assessment team to examine one-quarter of those residing in 50% of the villages after 1 week. This involved much more travel and manpower than the standard plan proposed in the 1967 WHO *Handbook for Smallpox Eradication Programmes in Endemic Areas* (SE/67.5 Rev.1), which suggested that 5-10% of the villages should be assessed.

Progress was slow. Smallpox vaccinators averaged only 25-35 vaccinations a day in 1969 and 40 a day in 1970. Those performing BCG vaccinations averaged somewhat less than half this number. Overall, productivity was one-tenth to one-third that of other programmes in Africa.

### Recurrent Epidemic Smallpox, December 1968

While national and WHO staff struggled with the logistics of initiating the vaccination campaign, cases of smallpox once again began to be reported in late December 1968 in Upper Nile Province. A surveillance team had not yet been constituted and so 2 WHO staff members were again sent temporarily to the Sudan to investigate. From their observations, it was apparent that smallpox had re-established itself in the country. The initially reported cases had occurred in villages near the Ethiopian border. The outbreak had spread westwards and northwards just as had happened earlier in 1968. However, careful epidemiological investigations suggested that this was not an importation from Ethiopia followed by localized spread, but rather the spread of smallpox from a number of endemic areas within the Sudan itself (*Wkly epidem. rec.*, 1969b). By the end of April 1969, the team had documented 119 cases in 4 provinces—Upper Nile, Blue Nile, Equatoria, and Khartoum. The beginning of the outbreak coincided with the beginning of the harvest season, when large numbers of seasonal workers began to travel from Upper Nile and Equatoria by boat, truck, train and on foot. Most of the cases were detected in special camps established for seasonal workers and at check-points for those in transit. It was clear that there were many more cases in villages, some in the southern areas afflicted by civil war, but in the absence of an organized reporting system, they were not being notified. The cases were of the mild variola minor type, only 3 deaths occurring among 119 patients. (These deaths are not recorded in the official figures given in Table 18.14.) Many patients were able to travel even when ill and thus readily disseminated the disease. The fact that half of all the cases were in persons over 15 years of age and that more men than women were affected (Table 18.17) reflected the spread of smallpox primarily among migrant labourers.

The investigators recommended that a surveillance programme should be established and a special campaign mounted to vaccinate seasonal workers in and *en route* to their camps. They believed that little could be done to vaccinate those in the southern provinces, but they reasoned that if the seasonal workers were well immunized, vaccinal immunity in sparsely settled rural areas of the south would

Table 18.17. Sudan: number of reported cases of smallpox, by age group and sex, January-April 1969

Age group (years)	Male	Female	Total	% of total for all ages

1-4	14	13	27	24
5-9	7	7	14	12
10-14	5	7	12	10
≥15	38	21	59	51
Total	66	49	115	100

be increased and, conceivably, the disease might die out.

The recommendations were not implemented but, as during the preceding year, the number of reported cases diminished; between the beginning of June and the end of November 1969, only 2 cases were notified (see Fig. 18.8).

### Major Epidemics Begin, 1970

In Upper Nile Province 2 cases were reported in December 1969, 3 cases in January 1970, and 124 in February. Smallpox was also introduced into the northern Sudan from Ethiopia. Steadily the disease spread across the country to infect all but Darfur Province. In June 1970, a central surveillance team was appointed under the direction of Dr Suliman, and by the end of the year, 1051 cases had been documented; most were detected by the surveillance team. Interestingly, adult cases continued to predominate, 55% being in persons over 15 years of age.

The vaccination campaign continued to progress slowly, its pattern of operation unchanged, as neither Sudanese nor WHO staff seemed able to devise an alternative operational approach. Continuing assessment showed that when vaccination had been completed in an area, consistently more than 85% and usually more than 95% of those under 5 years of age had a smallpox vaccination scar. Among older children and adults, the proportions were even higher, reflecting past vaccination efforts. BCG vaccination coverage, however, was usually in the range of 60-75% and sometimes lower. WHO regional smallpox eradication staff urged that BCG vaccination should be suspended until smallpox transmission had been interrupted, but, to the government, the policy of providing two vaccines simultaneously remained an

attractive one. The smallpox eradication staff turned for advice to the WHO Regional Adviser for Tuberculosis, who had originally advocated the plan. Unhelpfully, he concluded in his report: "Certainly, the least attractive approach would be to continue the *status quo*, that is smallpox vaccination from house to house and BCG vaccination at collecting points." He offered no alternative plan, concluding only with the advice: "Whatever the final solution, one should test-run the various approaches as envisaged... and select the most promising one."

By June 1970, 18 months after the programme had begun, only 5.3 million persons had been vaccinated, an estimated 68% of the population in the 3 provinces in which operations had been expected to be completed during the first year of the programme. Outside of these 3 provinces, the number of vaccinations recorded was equivalent to 5% or less of the population.

At the end of August, the programme stopped altogether when cholera cases were detected in the Sudan and the Ministry of Health decided to assign the teams to conduct a mass cholera vaccination campaign. Cholera vaccine offered little protection but was widely used nevertheless in many countries at that time. During November, no smallpox or BCG vaccinations were performed and, for many months thereafter a considerable number of teams and vehicles continued to be used for the administration of cholera vaccine. During December 1970, the smallpox-BCG vaccination campaign was gradually resumed but, as was noted in the populous Blue Nile Province, many villagers had left by that time to pick cotton. Entire villages were found empty or with very few residents. Vehicles were in critically short supply, some having been irreparably damaged by the bad roads, some remaining with cholera vaccination teams and some having been diverted to other uses by the Ministry of Health. In March 1971, the mass campaign finally concluded in the central provinces, more than 2 years after it had begun. The number of vaccinations reported to have been performed during 1969-1970 was greater than in 1968 (Table 18.18), but not commensurate with that expected of a staff of more than 500.

The vaccination campaign shifted to the northern provinces in 1971 and coincidentally the surveillance programme—such as it

Table 18.18. Sudan: number of reported vaccinations, 1968-1975

Year	Number of vaccinations

was—ceased when Dr Sulieman was re-assigned to organize the vaccination campaign in Kassala Province. The WHO regional office replaced the WHO smallpox adviser by another adviser who, like his predecessor, was an ardent proponent of mass vaccination, with no understanding of the importance of the surveillance-containment strategy despite intense efforts at persuasion by the WHO regional office and Headquarters staff. The contributions of these advisers to the field programme were further compromised by the fact that neither travelled frequently out of Khartoum.

By the autumn of 1971, smallpox transmis-

sion in Africa had been interrupted in all but 3 countries: Ethiopia, in which the programme had only just begun; Botswana, which had become reinfected that summer following an importation from South Africa; and the Sudan, whose programme was then in its fifth year. Cases in the Sudan were being reported from all provinces, although of greatest concern were the 3 in the south, in which no formal smallpox programme activities were being conducted and from which 55% of all cases were then being reported. Some cases in Uganda were also traced to this area.

To assess what, if anything, could be done, Dr Shafa, then assigned to the WHO Smallpox Eradication unit in Geneva, visited the southern provinces in late October. He determined that movement out of the main towns was restricted but convoys regularly travelled to various areas, including the health establishments, which, for a population of 2.5 million, were quite numerous (Table 18.19). None held stocks of smallpox vaccine. None reported smallpox cases regularly, but all stated they could readily do so by utilizing police and army radio. It was apparent that vaccination and the investigation of outbreaks were impossible in rural areas, but

Plate 18.7. A provincial smallpox eradication office in the northern Sudan in September 1973. By that time the programme had been reorganized primarily as a surveillance operation.

Table 18.19. Southern Sudan: number of health establishments, by category and province

much could be done in the main towns and in districts adjacent to health units. Learning that a year earlier cholera vaccine had been successfully administered throughout the area with the help of police and army personnel, Dr Shafa proposed that vehicles, vaccine and other necessary supplies should be sent to the south, and that personnel from the southern provinces, then working in the mass vaccination campaign in the north, should be transferred to staff surveillance teams. Vaccine was sent to the south but the smallpox eradication programme leadership remained preoccupied with the mass vaccination campaign in the north and little else was done.

### The Initiation of an Effective Surveillance-Containment Programme, 1971

As viewed by WHO Headquarters staff, the critical problem for the Sudan lay in establishing an effective surveillance and containment programme. For this to be done without the support of senior programme staff or the WHO adviser seemed unlikely. Nevertheless, more in despair than in hope, it was agreed

D. P. FRANCIS

**Plate 18.8.** Omer Sulieman (b. 1940) organized a central surveillance team in the Sudan in June 1970 which was disbanded in March 1971, when mass vaccination began in the northern provinces. He re-established a surveillance programme in January 1972 and transmission ceased by the end of the year. Subsequently, he was recruited by WHO and served as smallpox eradication adviser in Pakistan.

that a special seminar on surveillance would be conducted in December 1971 for physicians and senior sanitary inspectors in each province. Hope was expressed that some way might be found for Dr Sulieman again to be given responsibility for supervising surveillance activities. Replacement of the WHO adviser was proposed but the WHO regional office disagreed. However, the addition of a

### Vaccination Conducted by the Anyanya Resistance Movement

In 1970, WHO staff in Geneva were asked for vaccine by representatives of the Anyanya Resistance Movement, the rebel forces in the southern Sudan. They denied that smallpox was present in the area but were concerned that epidemics might occur. When asked how they could transport the vaccine, they indicated that they regularly took supplies north by road from Kampala, the capital of Uganda, and from there travelled on foot for 7-10 days into forest areas of the southern Sudan. Government staff could not reach these areas but, officially, WHO could provide vaccine only to Member governments. It was a quandary because, clearly, it was in everyone's best interest for this area to be better protected.

The dilemma was resolved by transferring vaccine to leaders of the resistance movement and recording the amount as "lost from inventory". Whether or not it was used properly was unknown until after March 1972, when the civil war ended. Sudanese staff found on investigation of outbreaks that the Anyanya had conducted quite extensive vaccination campaigns although, as they pointed out, many persons remained unvaccinated.

F. SHATA

**Plate 18.9.** Migrants crossing the White Nile River at Juba in the southern Sudan. Civil war in the southern provinces resulted in a flow of refugees into Uganda and Zaire, who nevertheless frequently returned to trade or to visit relatives. They were the source of many importations of smallpox into Uganda between 1969 and 1972.

second WHO adviser was accepted provided that WHO Headquarters could find the necessary funds.

To the surprise of all concerned, the December seminar proved to be the turning-point. As Dr Sulieman later observed, he appreciated for the first time how important surveillance and containment really were. Following the seminar, and over the objections of the WHO adviser, he resumed responsibility for the surveillance programme. With a remarkably imaginative and energetic group of public health officers serving as directors of provincial surveillance teams, he began to strengthen reporting, to search for cases and to investigate outbreaks throughout the central and northern provinces. Many outbreaks were discovered and contained. Where resistance to vaccination was encountered, vigorous measures were taken. For example, cooperation was poor in one village in Kordofan; the police surrounded it before sunrise, and vaccinators moved from house to house and room to room, searching and vaccinating. By April, virtually all cases were occurring among

travellers from the south, and in June the last cases were detected in the central and northern provinces.

At the end of March 1972, the government and the southern rebel forces—the Anyanya Resistance Movement—signed a treaty of reconciliation. In May, Dr Sulicman transferred his headquarters, including personnel and vehicles, to Bahr El Ghazal to begin work in the south. The rainy season was under way and travel in rural areas was difficult; in some it was impossible until October. In the latter areas, this period was used to construct detailed maps of the routes followed by migratory workers. An order was issued requiring all health units to report cases weekly; all chiefs, subchiefs, police stations, schools, forest and road workers were contacted and asked to report cases to these centres. Work was begun with 44 health staff who undertook a rapid house-to-house search throughout accessible areas.

Vaccination was performed only where outbreaks were encountered. By means of a scar survey, staff discovered that in most towns and villages along the way, 90% or

more of the population had been vaccinated. The cases found in these areas were generally on the periphery of towns and were quickly contained. However, many persons had moved deep into the jungle during the war. There, vaccinal immunity was far lower and rumours of outbreaks were difficult to trace. Accordingly, former Anyanya military personnel were recruited and given bicycles to search for cases in remote areas—areas well known to them. Returning refugees were vaccinated at resettlement camps; health units throughout the 3 provinces were given supplies of vaccine and instructed to vaccinate both those attending centres and others living nearby. In June 1972, the programme was extended to Equatoria and Upper Nile Provinces. By the end of September 1972, 17 outbreaks had been discovered in Bahr El Ghazal, 10 in Equatoria and 1 in Upper Nile. Surprisingly, the largest of these consisted of only 25 cases. The cooperation of those living in the area was illustrated by the fact that in Equatoria, the last 2 outbreaks were reported by a villager and a chief who, respectively, walked 45 and 70 kilometres to report cases. In October, the rains stopped and the systematic search was extended throughout the rural areas. Teams travelled on northward-bound river steamers to search for cases and to vaccinate embarking passengers, and other check-points were established. Fifty medical students from the School of Medicine in Khartoum joined the programme, working in teams with vaccinators to search for outbreaks and to contain them. Only 5 additional outbreaks were discovered in Bahr El Ghazal Province and 1 in Upper Nile Province, although numerous patients were found who

had experienced the onset of illness many weeks previously. Fig. 18.8 shows the number of cases of smallpox by week of report and by week of onset. Interestingly, the last case was discovered on 17 December 1972 in a village called "Malek", which is the local name for smallpox. One additional patient who had been infected in Ethiopia developed smallpox on 23 December in northern Kassala Province but he was the last.

On Dr Shafa's recommendation, a former operations officer from the Ethiopian programme, Mr James Lepkowski, and a former medical officer from the western Africa programme, Dr Donald Francis, were assigned by WHO to Juba in Equatoria Province in November 1972 and January 1973 respectively. A thorough systematic search for cases was organized throughout the southern provinces and subsequently in areas bordering on Ethiopia. It seemed inconceivable that transmission had been stopped throughout such a vast area, in which, less than a year before, smallpox had been reported from all provinces. However, no cases could be found (WHO/SE/73.60, Lepkowski et al.; WHO/SE/74.67, Bassett et al.). During the course of a single year, Dr Sulieman had brought order out of chaos and had succeeded in stopping transmission before additional manpower from WHO had had time to arrive on the scene. In September 1973, a village-by-village search was conducted throughout the country, but again no cases were found.

Smallpox remained widely prevalent in Ethiopia, however, and, as previously noted, many people travelled between the Sudan and Ethiopia. Special surveillance units were posted to migrant labour and refugee camps,

Fig. 18.8. Sudan: number of reported cases of smallpox, by month, 1967-1973, with cases plotted according to week of report and week of onset for 1972.

**Plate 18.10.** Donald P. Francis (b. 1942), an epidemiologist, was the WHO smallpox eradication adviser in the Sudan from January 1973, arriving just after the occurrence of the last known case in the country. With the Sudanese staff, he helped to organize a national surveillance system to protect against the effect of importations of smallpox from Ethiopia.

search workers were assigned to travel on the river steamers and special search teams covered the border areas. Many rumours of cases were received, but none proved to be smallpox. In September 1972, during a seminar in Addis Abeba, it was proposed that Sudanese and Ethiopian teams should be granted permission to cross the border without hindrance when undertaking search operations. Both governments agreed and, thereafter, Sudanese teams investigating rumours of cases, sometimes at the request of Ethiopian programme officers, travelled far into Ethiopia. In November 1973 and in March 1974, the teams undertook special search and vaccination programmes over extensive areas, difficult of access, in Ethiopia.

**Table 18.20.** Sudan: results of vaccination scar survey, by age group and province, 1975-1976

Region and province	Number examined	Percentage with vaccination scars			
		<1 year	1-4 years	5-14 years	≥15 years
Northern region:

Equatoria	2 930	77	88	82	98
Bahr El Ghazal	6 438	15	25	75	71

The level of vaccinal immunity attained in the Sudan had been assessed in the central and northern provinces and found to be uniformly high, although doubt was expressed whether the surveys had been properly conducted. Not until 1975-1976 was a reliable cluster sample survey performed. It was found that coverage, in general, was high except in Bahr El Ghazal, in which systematic mass vaccination had not been conducted (Table 18.20).

The age and sex distribution of cases in the Sudan in 1970 was most unusual in that nearly half of all cases for which data are available were in adults, of whom 60% were male (Table 18.21). A large proportion of the recorded cases that year occurred among adult migrants coming from endemic areas in the south and in labour camps. As the disease continued to spread in the north, larger proportions of children were affected. Finally, in 1972, as cases in southern endemic areas were investigated, more cases were found in children, and the age distribution more nearly approximated to that found in other endemic areas: 15% of patients were under 5 years of age, and 48% were aged 5-14 years.

### Investigation of a Suspected Case

The problems of travel are well illustrated by extracts from a report of the investigation of a case by Dr Satnam Singh, a WHO epidemiologist in the Sudan. On 10 September 1975, the smallpox programme office was notified of a suspicious rash in a 40-year-old woman seen at a dispensary in the village of Geissan, on the border of the Ethiopian region of Gojam, where many cases of smallpox had been occurring. Because of drought in their own country, many Ethiopians had begun to visit Geissan to obtain sorghum. The report stated that the patient had been isolated and 12 family members vaccinated as well as 980 residents and visitors in the village. The report had been delivered to the nearest telegraph station, Damazien, 156 kilometres away, after a 5-day journey on foot. The telegraph line being out of order, it was not until 9 September that the provincial medical officer received the message. He then telephoned in the report.

A sanitarian, Mr Abdul Gadir El Sid, joined Dr Singh on the first available flight to Damazien on 13 September. There the Assistant Commissioner provided them with a 4-wheel-drive all-terrain vehicle (a UNIMOG) and a 4-wheel-drive army vehicle for a trip expected to take 10–15 hours. They were accompanied by smallpox eradication workers and a few army personnel. As Dr Singh wrote: "From the moment we left Damazien, we realized it would be difficult to traverse the water-logged muddy track overgrown with 12-foot-high grass. Regularly, the army vehicle, despite its more powerful engine, got stuck in the sticky mud and had to be pulled out manually, aided by cables attached to the UNIMOG. The multiple running streams (*kbors*) that criss-crossed the track along the west bank of the Blue Nile caused additional delays. Some required reconnaissance on foot above and below the track to find a suitable crossing and the same was done when the regular track was waterlogged for long stretches. Detours were made through the tall grass fields and bushes. After one and one-half days' travel and a one-night halt, we had only covered a quarter of the distance and found ourselves with only the UNIMOG operational—the other vehicle having been irreparably damaged. It was decided that a few should return to Damazien to mount another expedition including a tractor.

"The return journey to Damazien was worse for it had rained in the meantime. After a one-night halt in a village, we reached Damazien at 9:00 p.m. on 16 September . . . and on the 18th we started for Geissan with one tractor, the same UNIMOG and a relatively new army vehicle with a mechanic and spare parts.

"To have a tractor was a boon. The vehicles when stuck were pulled out quickly. In the meantime, however, more rain fell and in consequence more swollen rivulets and *kbors* had to be crossed. On the 19th, we had to abandon the army vehicle and pushed ahead with the UNIMOG and the tractor. In spite of the rainstorm, the river was only waist deep but with a fast current. Our vehicles forged through with manual help from the villagers. The rest of the journey was uneventful except that the terrain near Geissan is so hilly that in a few places there was a real danger of the vehicles turning over into the valley. We got a rousing welcome from the residents of Geissan, a community of 1500 persons, when we reached there at 8:30 p.m. on the 21st.

"The patient's rash had healed, but clinical and epidemiological examination clearly indicated that it was a case of chickenpox.

"We began our return journey on 24 September. The return trip was even slower as more rain had fallen. On 25 September, we reached a *kbors* so heavily flooded that several days' wait would be required for the waters to recede. The writer and Abdul Gadir decided to complete the trip by boat. We obtained a small leaky fishing canoe and paddled down the flooded Blue Nile endeavoring to avoid the larger, frequent whirlpools. After 4 hours, we pulled ashore at a village to camp for the night and there were able to get a wooden boat with motor which took us to Damazien. On the following day, 27 September, 14 days after arrival, we took the once-weekly air flight back to Khartoum."

During most years and in most age groups cases were more frequent in males than in females. For adults, this was to be expected because the migrants were more often males. For younger age groups, there is no ready explanation for the sex differential. However, the data must be interpreted with caution because outbreaks were not thoroughly investigated until 1972 and, even then, investigation in the tropical forest areas was by no means complete and, in some areas, cases remained undetected because they were hidden from the investigators.

### CONCLUSION

The smallpox eradication programmes in the Sudan and Zaire, two of Africa's largest countries, present a study in contrasts. When the programme began in Zaire, smallpox was highly endemic. The population was poorly vaccinated, and its professional staff and health infrastructure were at an early phase of development. Conversely, the Sudan in 1967 was free of smallpox, vaccinal immunity in the central and northern provinces was high and the country's health structure was comparatively advanced.

Both countries endeavoured to execute nation-wide vaccination campaigns employing both BCG and smallpox vaccines, the first programmes to administer the two antigens simultaneously. It was expected that there might be operational difficulties in conducting a time-limited mass campaign which required field activities to accommodate the administration of smallpox vaccine to the entire population and the administration of BCG vaccine to children and adolescents. WHO smallpox staff argued that it would be preferable to begin field operations using only one antigen, and to add the second after the programme had become established. Those responsible for tuberculosis control were anxious that BCG vaccination should be incorporated in the programme from the outset, arguing that to administer two vaccines entailed little more in cost or effort than to administer one. This view prevailed.

As was foreseen, both programmes did experience substantial problems in administering the two antigens simultaneously. Zaire, however, was soon able to resolve the difficulties by using jet injectors for both vaccines and to administer them to groups assembled at collecting points. In little more than 3 years, a

country-wide programme had been completed with a staff which, at its maximum, numbered 234 persons. In the Sudan, the assembling of the general population at collecting points was not well accepted, thus precluding the effective use of jet injectors. Smallpox vaccination was therefore conducted from house to house with the bifurcated needle, while BCG vaccine was administered by needle and syringe to children at collecting points—a system that never worked well. Despite a staff of more than 500 persons, the programme proceeded slowly and, in fact, was terminated before vaccination had been completed throughout the country.

Acceptance and understanding of the concept of a national programme for the surveillance and containment of outbreaks likewise differed in the two countries. In the Sudan, as was the practice in other countries with a comparatively well developed infrastructure of health services, provincial and district health officers had primary responsibility for disease control. These medical officers differed greatly in their abilities, their understanding of epidemiology and their perception of priorities and, with no national surveillance unit to provide support and guidance, most controlled such smallpox outbreaks as were discovered in the traditional manner—by mass vaccination. Efforts to improve reporting and to investigate outbreaks to ascertain the sources of infection were uncommon. The belief that no special national surveillance programme was required was reinforced by the fact that the Sudan had succeeded in interrupting smallpox transmission in 1963. In the absence of a national surveillance programme, the disease, following its reintroduction in 1970, spread to almost all parts of the country. When a surveillance programme commenced in 1972, transmission was stopped within 12 months.

By contrast, in Zaire, in which the health structure was less sophisticated and not so well established, the concept of a national surveillance programme was more readily accepted. This proved to be the experience in many of the less well developed countries. Although the establishment of an effective surveillance programme was greatly delayed, owing to the lack of experienced personnel, the programme in Zaire succeeded in interrupting transmission some 18 months before that in the Sudan.

The contributions of WHO and other international agencies were critical to the success of both programmes, but in neither country were they as effective as they might have been. In Zaire, transmission might have been interrupted far sooner had the promised WHO resources been provided in a timely manner; in the Sudan, the assignment of

effective advisers might well have helped to prevent the re-establishment of smallpox.

Whatever the problems, the attainment of eradication was a notable achievement in both countries, given their size, the formidable difficulties of transport and communication and the persistence of civil disorder.

### INTRODUCTION

This chapter describes the development of smallpox eradication programmes in 5 contiguous countries of eastern Africa—Burundi, Kenya, Rwanda, Uganda and the United Republic of Tanzania<sup>1</sup> (Fig. 19.1). In 1970 their combined population amounted to 42 million and their total land area to 1 818 000 square kilometres. In comparison, adjacent Zaire to the west had half as large a population in 1970 but an area 25% greater.

The infrastructure of transport and communication services was better developed than in the countries of western and central Africa; moreover, government and private

health centres, clinics, dispensaries and hospitals were more numerous. Vaccination, with liquid vaccine, had been practised more or less extensively throughout most parts of these countries for more than 50 years, most vaccinations being given when outbreaks of smallpox occurred. Some health facilities offered vaccination to any patients attending them, but the vaccine was generally stored at room temperature and its potency was therefore presumably low or nil.

Among the many health problems in these countries, smallpox in the early 1960s had not been of high priority except in Tanzania. Epidemics of variola major had occurred in previous decades but, more recently, in all countries except Tanzania, variola minor with a low case-fatality rate prevailed. For example, during the period 1961-1965, 1182 cases with only 6 deaths were reported from Kenya, and between 1961 and 1964 Uganda recorded 1960 cases and 4 deaths. However, Uganda in 1965 and Kenya in 1966 began to

<sup>1</sup> The United Republic of Tanzania was formed in 1964 by the union of Tanganyika, Zanzibar and Pemba. Although its official name is used elsewhere in this book, it is, for brevity, referred to as "Tanzania" in the text and tables of this chapter. The islands of Zanzibar and Pemba experienced no smallpox and conducted no special eradication programme.

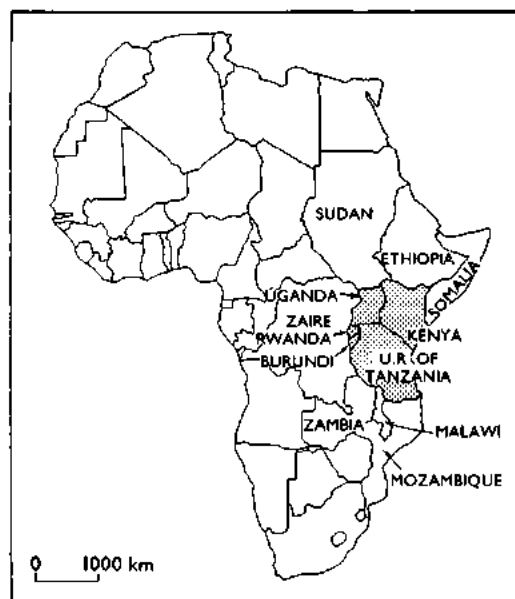

Fig. 19.1. Eastern Africa and adjacent countries.

experience an increasing number of deaths due to smallpox and consequently took a greater interest in controlling the disease. In Tanzania, a more severe form of smallpox had been prevalent, with recorded case-fatality rates of 5–7%. Even so, the problem was not large when viewed against the greater threats posed by malaria, tuberculosis and several other infectious diseases. Vaccination campaigns, however, were an integral part of public health activities because of the fear of recurrence of epidemics of the virulent *variola major*. With substantial commerce and travel between eastern Africa and Asia and the generally held belief that severe *variola major* prevailed elsewhere in Africa, there was reason to maintain adequate levels of vaccinia immunity.

After 1967, when the Intensified Programme began, all 5 countries agreed to undertake eradication programmes which would include systematic national vaccination campaigns employing, for the first time, freeze-dried vaccine of acceptable quality. WHO provided each country with advisers, all the requisite transport, equipment and supplies (including vaccine) and reimbursed the governments for the costs of petrol and vehicle maintenance. The countries made available a small cadre of national personnel, but little else. Each conducted effective national smallpox vaccination campaigns,

which, in Kenya, Rwanda and Tanzania, were carried out in conjunction with the administration of BCG (antituberculosis) vaccine to children under 15 years of age.

Smallpox vanished quickly, transmission being interrupted by the end of 1970, well before the systematic vaccination campaigns reached most areas and, indeed, before effective programmes of surveillance and containment had been developed. After 1970, importations from the Sudan occurred along Uganda's northern border, and importations from Ethiopia and Somalia along Kenya's north-eastern borders. The outbreaks were all in sparsely populated areas; none resulted in large numbers of cases or persisted for long periods.

The mass vaccination campaigns differed somewhat in character from one country to the next, as each was adapted to the nature of the health services and the political structure of the country concerned. Information about the epidemiological characteristics of smallpox in eastern Africa is scarce, however, because little was done to improve the national reporting systems or systematically to investigate suspected cases until after 1970, when transmission had been interrupted.

The rapidity and ease with which smallpox transmission was interrupted in these countries, as well as many others in Africa, were surprising. At the time, the situation served to engender an unwarranted confidence that smallpox eradication could be readily achieved with only a modest incremental investment of resources, even in programmes in which performance was marginal. In Africa itself—notably in Ethiopia, Somalia and the Sudan—this belief later proved to be unfounded.

### SMALLPOX CONTROL ACTIVITIES BEFORE 1969

In 1967, when the Intensified Smallpox Eradication Programme began, the countries of eastern Africa reported a total of only 2221 cases (Table 19.1). In a population which then numbered almost 38 million, this figure was not large. Moreover, the number of recorded cases was diminishing rapidly, from 5607 in 1965 to 4163 cases in 1966. Of the 5 countries, only Rwanda reported no cases whatsoever during the period 1966–1968 but it was provisionally categorized as an endemic country, since it was difficult to believe that a

Table 19.1. Eastern Africa: population and number of reported cases of smallpox, 1965-1977

<sup>a</sup> No cases officially recognized.<sup>b</sup> Imported cases.<sup>c</sup> Including 23 cases resulting from importations.

country completely surrounded by heavily infected areas could be free of smallpox. Not until 1969 was it learned that it was government policy to report only cases that were confirmed by laboratory examination. Because no specimens were examined, no cases were reported.

Vaccination was provided routinely in all countries, the number performed annually being equivalent to about 10-20% of the population (Table 19.2). Undoubtedly many of the vaccinations were unsuccessful because of the use of vaccine that was subpotent at the time of administration. Kenya, Tanzania and Uganda used liquid vaccine produced at the Medical Research Laboratory in Nairobi or at the Lister Institute, England. Although usually stored under refrigeration in the capital city, the vaccine was exposed to ambient temperatures during shipment and rarely refrigerated at any of the intermediate distribution points or in health centres. This was a problem, because liquid vaccine becomes inactive within 3 days or less at ambient temperatures when it is not refrigerated. No data are available regarding the proportion of successful vaccinations because vaccinees were not examined to determine whether their vaccinations had taken. Until 1965, Rwanda and Burundi also used liquid vaccine, produced at a laboratory in Rwanda or imported from Belgium. In 1965, the Rwanda laboratory began producing a reasonably satisfactory freeze-dried vaccine, but the vials in which it was distributed were so large that the amount of vaccine each contained was sufficient, after reconstitution,

for 600 doses or more. This was not much of an improvement, because freeze-dried vaccine, after reconstitution, loses its potency within 24 hours unless it is refrigerated, and few health centres had refrigerators which functioned properly. Rarely did any health unit have cause to vaccinate more than a few persons a day but the staff continued to use the reconstituted vaccine until each vial was empty. In 1968, for example, a WHO smallpox eradication adviser observed at a hospital in Rwanda that a vial containing vaccine reconstituted 3 months earlier was still in use.

In each of the countries, mass campaigns were conducted from time to time in specific areas when epidemics occurred. For such campaigns, vaccine was shipped to the field direct from the laboratories and was more likely to have been of adequate potency at the time of administration than vaccine which had been kept for weeks or even months at health centres. Only one country-wide mass vaccination campaign—in Uganda—had been carried out since the 1950s. In 1965, the number of reported smallpox cases and deaths in Uganda increased. The Ministry of Health, fearing epidemic variola major, launched a national campaign. Between August 1965 and February 1966, 7.5 million persons were vaccinated, a total equivalent to more than 90% of the country's population at the time. The cost of vaccine alone, most of which was purchased from the United Kingdom, amounted to more than US\$200 000. A survey conducted by Ladnyi in 1966 revealed vaccination scars in 88% of children in primary

schools, but in only 61% of people attending clinics at 6 hospitals. The examination of 33 patients with smallpox revealed that 8 had been unsuccessfully vaccinated 1-3 months before. It was apparent that the campaign had been far less successful than the coverage might suggest.

The impression that a more severe form of smallpox had appeared in Uganda is borne out by the available records. Up to 1965, deaths from smallpox had been infrequent in Uganda, but in 1965 the case-fatality rate increased to nearly 5% and remained high until transmission was interrupted (Table 19.3). During the following year, the case-fatality rate in Kenya also increased, with both cases and deaths occurring primarily in areas adjacent to Uganda. Kenya, too, undertook a mass campaign—in Nyanza Province, which borders on Uganda. Between March and April 1966, 670 000 persons were vaccinated. In the same year, 500 000 people in Burundi and 6 million in Tanzania were vaccinated during mass campaigns.

From 1966 onwards, the case-fatality rates in Uganda and Kenya were characteristic of those observed with the African strain of variola major. This strain had been prevalent in neighbouring Tanzania and Zaire, from which it had presumably been introduced. Nothing can be said of the status of Rwanda or Burundi at this time, because no cases were officially recognized by Rwanda and deaths were not registered in Burundi.

#### AGREEMENTS TO UNDERTAKE ERADICATION PROGRAMMES

In October 1965, Ladnyi was assigned by WHO to Nairobi as an intercountry smallpox adviser in the eastern portion of Africa. He was responsible for providing advice on the development of smallpox eradication programmes to the 19 countries of eastern, central and southern Africa in WHO's African Region that lay to the south of the Sudan, Ethiopia and Somalia (which at that time all formed part of the Organization's Eastern Mediterranean Region). An epidemiologist based in Liberia was assigned similar functions in the western portion of Africa. The initiative by the Regional Office for Africa to provide regional smallpox eradication programme advisers antedated the decision of the Nineteenth World Health Assembly in May 1966 to allocate special

WHO

**Plate 19.1.** In Rwanda and throughout eastern Africa, mass vaccination had traditionally been used to control the spread of smallpox. Villagers willingly assembled at collecting points to be vaccinated.

funds for eradication; they were, in fact, the first WHO regional smallpox eradication staff to be appointed. Ladnyi immediately embarked on a series of visits to each of the countries, beginning in 1966, with Burundi, Kenya, Malawi, Tanzania, Uganda and Zambia.

At the start, he could do little except offer advice, since the resources allocated to the smallpox eradication programme by WHO were so limited. Moreover, because most countries did not consider smallpox an important problem, few were interested in

developing programmes, or, indeed, were able to do so without special assistance.

The above-mentioned decision of the Nineteenth World Health Assembly to allocate funds for smallpox eradication from the Organization's 1967 regular budget made it possible to launch many national programmes. Surprisingly, however, except for those from Zaire and Zambia, no requests for assistance were received by WHO from any of the countries in central, eastern or southern Africa. Meanwhile, during 1966 and 1967, programmes throughout western

<sup>a</sup> Cases Imported from the Sudan and Rwanda.

Africa began to develop with assistance provided by the USA (see Chapter 17). Smallpox eradication staff from WHO Headquarters asked the regional office to contact the eastern and southern African countries to ascertain their interest in developing eradication programmes. However, the regional office pointed out that, as a matter of policy, it responded only to requests for assistance initiated by the countries themselves. In part, this policy derived from the views of the Director-General of WHO. In meetings with his regional directors in 1966, he had urged extreme caution about imposing another mass programme on Member states, after the experience with malaria eradication. The regional directors, in turn, had conveyed this to the WHO representatives in the countries themselves. Because the Director-General regarded smallpox eradication as improbable, he believed that such a programme would only divert national resources from more important activities (see Chapter 10). The WHO smallpox eradication staff in Geneva, on the other hand, maintained that the decision to undertake global smallpox eradication had received the unanimous approval of the World Health Assembly; funds had been appropriated for this purpose and thus it seemed only reasonable to contact the endemic countries to assess their intentions and needs. To expect the African countries themselves to respond spontaneously to new programme directions seemed unrealistic. All were newly independent, beset with problems and struggling to bring order into chaotic bureaucracies. These arguments were, however, of no avail.

Ladnyi, as a member of the regional office staff, had his hands tied; there was little he could do to overcome the apparent impasse in the initiation of eradication programmes in

central, eastern and southern Africa, without directly flouting the policy of the regional office. The problem of how to approach the countries was resolved when the regional office agreed that a medical officer from Headquarters, Dr Stephen Falkland, accompanied by Ladnyi, could visit a number of African countries early in 1967 so that the Director-General could report to the World Health Assembly in May of that year on each country's smallpox status and intended activities, if any, in accordance with the Assembly's request of 1966. Dr Falkland was specifically directed that under no circumstances should he propose to any country that it should undertake a programme. In the event of a display of interest, however, he carried with him a draft letter requesting assistance, prepared for the signature of the minister of health, as well as a draft plan of operations which could be readily adapted to the specific conditions of each country. He made brief visits to Burundi, Kenya, Rwanda, Tanzania and Uganda, all of which expressed interest in initiating smallpox eradication programmes and which forthwith sent formal requests to WHO for assistance.

Of the 5 countries dealt with in the present chapter, only Tanzania viewed smallpox as an important problem. However, to undertake eradication programmes, it was unnecessary for the governments concerned to commit substantial national resources. For each programme WHO agreed to provide an adviser, vehicles (including in some instances, motor cycles and bicycles), refrigerators, camping equipment, vaccine and bifurcated needles, as well as a sum of money to cover the costs of petrol and vehicle maintenance. The country's obligation was primarily to provide a small cadre of national staff. To offset the

<sup>a</sup> Excluding the cost of vaccine.

additional expenditures necessary for salaries of these workers, WHO made available vaccine and transport, which hitherto had been at the charge of the government. In all, the Organization provided US\$1 450 839 in support of programmes in eastern Africa, a sum equivalent to US\$0.01–0.07 per head of population (Table 19.4). The individual governments disbursed no more—and in most cases less—to eradicate smallpox than they had spent on controlling the disease.

### PROVISION OF FREEZE-DRIED VACCINE

The acquisition of adequate supplies of freeze-dried vaccine and their distribution presented a problem to WHO throughout most of the global eradication programme (see Chapter 11). In the countries of eastern Africa, as well as many of those in central and southern Africa, there were unique difficulties which required special solutions.

Attempts were made in all endemic areas to promote the local production of vaccine, but it was not practicable for every country to do so because of the considerable cost and effort needed to establish and maintain a laboratory. For some 50 years, the Kenyan Medical Research Laboratory had been producing liquid vaccine, which it sold to Tanzania and Uganda. Thus, it seemed logical to supply this laboratory with equipment and consultant assistance so that it might serve as a regional resource for the production of freeze-dried vaccine. UNICEF provided US\$20 000 for the necessary equipment and in January 1967 WHO made available the services of a consultant. By April 1967, the laboratory, directed by Dr Geoffrey Timms, had succeeded in producing 4 experimental batches of freeze-dried vaccine and by October 1968 was producing sufficient vaccine of a consistently high quality to meet all Kenya's needs. As production increased, it became possible to supply neighbouring countries, but herein lay a quandary. Kenya needed to charge for the vaccine to recover production expenses. WHO's stock of vaccine, however, was being provided through voluntary contributions and then distributed free of charge to all endemic countries to encourage its use. Unless this had been done, many governments, lacking reserves of convertible currency, would have continued to use locally produced liquid vaccine. The purchase of vaccine from

Kenya by WHO was not feasible, because several producers in Europe were anxious to sell vaccine and such a move might have endangered the donation programme (see Chapter 11); thus, WHO had adopted the policy of purchasing no vaccine whatsoever. The problem was ultimately solved by supplying Kenya with almost all the materials needed for vaccine production, thus enabling it to produce additional vaccine which could be donated to WHO for use in other African countries. In all, WHO provided some 31 million doses of vaccine for use in the countries of eastern Africa (Table 19.5), of which 15 million doses were produced in Kenya.

The distribution of vaccine in a timely manner to the numerous African countries was a factor that had to be taken into account. Vaccine was in short supply throughout most of the eradication programme, and it was therefore not possible to stockpile large reserves in the endemic countries. With the uncertain schedule of vaccination campaigns, the shipment of vaccine had to be planned in advance. Vaccine donated to WHO during the early years came primarily from Europe or North America and was maintained in a cold-storage warehouse in Geneva. With the extensive air transport network centred in Geneva, it was not difficult to deliver vaccine anywhere in the world at 48 hours' notice. Vaccine donated by Kenya, however, was shipped direct to neighbouring countries to minimize transport costs. Distribution systems were thus in place for national programmes to be sustained without large stockpiles.

A problem which had to be tackled was that of communication through the official channels of WHO. For an African country to obtain vaccine, the standard procedure called for a request to be directed to the WHO

Table 19.5. Eastern Africa: freeze-dried vaccine supplied through WHO, from 1967 onwards (thousands of doses)

After 1974	1 260	4 153	1 148	241

Regional Office for Africa in Brazzaville, which would forward it to Geneva. Communication between African countries, however, was often much slower than communication between Africa and Europe, and inevitably there were delays in processing the request within the regional office. A telegraphic request through official channels sometimes took 4-8 weeks before being received in Geneva. Meanwhile, field programmes came to a halt. The difficulty was resolved simply by sending 2 telegraphic messages—an official one to the regional office in Brazzaville and an unofficial one to Geneva, on which action was promptly taken.

Freeze-dried vaccine which had been contributed to WHO was made available to several of the countries for use in their health services even before their formal mass vaccination campaigns began (Table 19.5). This vaccine was first used by Burundi and Tanzania at the end of 1967 and by Uganda early in 1968. Kenya began using locally produced freeze-dried vaccine in October 1968. Tanzania reverted briefly to the distribution of liquid vaccine during November 1968, when it received a bilateral donation of 300 000 doses, but fortunately no further contributions of this type were received. Rwanda continued to use its own locally produced freeze-dried vaccine until early 1969, when the government was persuaded to stop production and to destroy all existing stocks.

## THE VACCINATION CAMPAIGNS

Except for a pilot programme in Tanzania in 1968, during which 350 000 persons were vaccinated, none of the vaccination campaigns began until 1969. Meanwhile, the number of reported cases of smallpox in Kenya, Tanzania and Uganda fell sharply (see Table 19.1), from 3800 in 1966 to 2147 in 1967 and to only 597 in 1968. Rwanda, during this period, did not officially recognize cases of smallpox; and little can be said about trends in Burundi, whose reporting system was less adequate than the others. During these years, little had been done to change the reporting systems and there was no organized surveillance-containment activity. However, the trend in incidence was steadily downward and systems which had detected many cases in prior years were now reporting very few. The mass campaigns in Uganda, Burundi, parts of Tanzania, and in Nyanza Province, Kenya, in 1965-1966 were undoubtedly responsible in part for the decrease in the number of reported cases. Perhaps of greater importance was the provision of freeze-dried vaccine for use by the health services in the control of outbreaks and in the limited routine vaccination programmes in which some health centres were engaged.

However, as we shall see, the vaccination campaigns in Kenya and Uganda began *after* transmission had apparently been interrupted; in Tanzania, only 88 additional cases

occurred after the beginning of the campaign, of which 23 are known to have resulted from an importation from Zaire (Table 19.6). The endemic spread of smallpox stopped only 13 months after the programme had begun in Rwanda and after 17 months in the case of Burundi.

The most heavily infected regions in 1967-1968 lay on the shores and in the vicinity of Lake Victoria (Fig. 19.2) and in the south-eastern area of Tanzania near the border with Mozambique. The region around Lake Victoria was also one of the most densely populated. As programmes began in 1969, Kenya

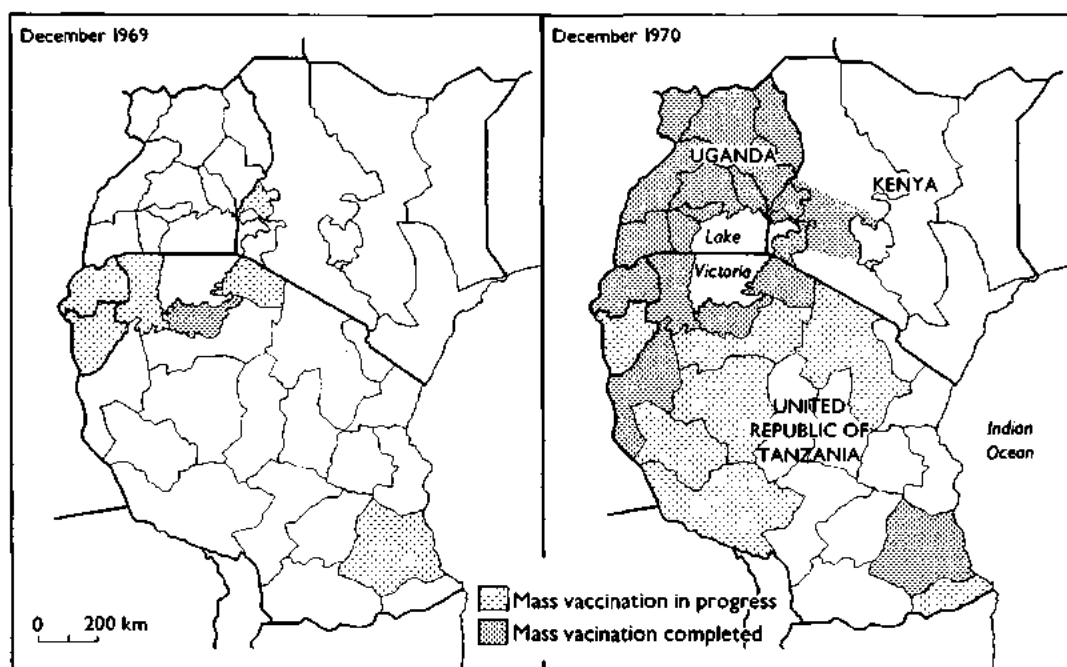

Fig. 19.3. Eastern Africa: status of vaccination campaigns, by administrative area, December 1969 and December 1970.

and Tanzania concentrated their efforts specifically in these areas (Fig. 19.3).

### Kenya

A WHO technical officer from Belize, Mr Henry Smith, was recruited to assist in the development of the Kenya programme. He arrived in September 1968 and continued with the programme until February 1974. From October 1968 to the end of May 1969, Mr Smith visited all provincial and district headquarters, beginning with those in the west, whence cases were being reported, to demonstrate the use of the new bifurcated needle and the freeze-dried vaccine. At the time of his visit, stocks of liquid vaccine were replaced with freeze-dried vaccine. Staff in the districts were then given responsibility for training those in peripheral units. In Kenya at that time there were 163 health centres and 350 dispensary clinics; their staff reported having vaccinated 1.5 million persons in 1968 and 948 000 in 1969—about 25% of the population in all.

The beginning of the mass vaccination campaign had to await the delivery of vehicles, which usually arrived 12–18 months after they were ordered. The vehicles were

Plate 19.2. Henry C. Smith (b. 1935) served as a WHO technical officer for smallpox eradication in Kenya, 1968–1974, before joining the programme in India.

delivered in the spring of 1969 and the programme began in October in Western Province, one of two small but densely populated south-western provinces inhabited by 40% (4.5 million) of Kenya's population. Kenya's last known case of endemic smallpox

occurred 4 months before the programme began.

Initially, the staff consisted of 2 supervisors assigned from the health services and 18 Kenyan National Youth Service Volunteers, who had completed elementary school and had undergone a 1-month training course. The team progressed from district to district. Three weeks before it was to begin work, Mr Smith, or sometimes the national programme director, met the district medical officer and health inspector to plan the campaign. Within the district, vaccinations were given to the inhabitants of one sublocation after another—a sublocation being a unit ranging in population size from a few hundred to 4000 and administered by a subchief. An assistant health inspector who worked in the area contacted each subchief to explain the purpose of the programme and to select a place of assembly for each sector at which approximately 300 persons would be expected to forgather. In the interests of economy of operation, the entire team worked in only one sublocation or a few adjacent sublocations each day. Assembly points included hospitals, health centres, dispensaries, schools, markets, chiefs' houses, shops, bus stops and well-heads. A few days before vaccinations were to be carried out, the subchief informed people of the schedule and the location of assembly points. Teachers were asked to pass on the details to parents and pupils. On the appointed day, 2 vaccinators (or more, if attendance was expected to be sizeable) were dispatched to the selected locations by Land Rover. One performed vaccinations while the other kept a simple tally by age group of the vaccinees. The vaccination centres were kept open throughout the entire day in order to give people sufficient time to attend, some being obliged to walk as far as 5 kilometres.

Because of the small number of staff, the vaccination campaign progressed so slowly

that, by the spring of 1970, it was estimated that 10 years would be required to complete it. Accordingly, it was agreed that more National Youth Service Volunteers should be recruited and more supervisors assigned. By the end of 1970, the staff complement had grown to 50 vaccinators, 18 drivers and 8 health inspectors. In addition, it was agreed that when a team was in an area, local health staff who could be spared would work with it. The resources provided to the programme are shown in Table 19.7. With the increased complement of personnel, it was eventually possible to work in 10 districts simultaneously.

In May 1970, it was decided to administer BCG vaccine concurrently with smallpox vaccine to children under 15 years of age, and from then on the vaccinators worked as 2-man units. One vaccinator administered smallpox vaccine in one arm, using the bifurcated needle, and one administered BCG vaccine in the other arm, using a needle and syringe, and tabulated the numbers vaccinated. With this staff, between 400 000 and 500 000 smallpox vaccinations were performed monthly. By the end of 1970, the vaccination schedule had been completed in Nyanza and Western Provinces as well as in portions of the neighbouring Rift Valley Province (see Fig. 19.3). In other parts of Kenya the population was vaccinated during 1971 and, finally, the coverage was extended to the numerous inhabitants of Nairobi and its surroundings in 1972. In all, 10.5 million vaccinations were performed by the mobile teams and 5.6 million by the established health units during this period.

The only departure from the routine occurred in March and April 1971, when 2 outbreaks, one of 45 cases and one of a single case, occurred in the north-eastern part of Kenya as a result of importations from Ethiopia (see Fig. 19.4). The mass vaccination

<sup>a</sup> During one period of 6 months.

campaign in this area had been scheduled to begin in April and last throughout June 1971, but its date of commencement was advanced to March. Subsequently, 6 vaccination/case-search rounds were conducted in this and 5 other northern districts that bordered on Ethiopia and the Sudan and were considered to be at high risk.

Except for Rwanda, none of the 5 countries followed the programme for assessment recommended in the WHO *Handbook for Smallpox Eradication Programmes in Endemic Areas* (SE/67.5 Rev.1). The handbook called for an assessment team to visit a 10% random sample of villages 1-2 weeks after vaccination to determine coverage and the proportion of people successfully vaccinated. As was the case in a number of countries, health officials resisted the diversion of personnel and vehicles from the vaccination campaign itself. To determine coverage in Kenya, the number vaccinated was simply compared with the estimated population in the area—an unsatisfactory procedure in a country where census data were so imprecise. Approximately 100 children were examined one week after vaccination to determine whether a sufficient proportion had been successfully vaccinated. Definitive information about the degree of success of the vaccination campaign did not become available until the conclusion of the programme, when, in 1972, 2 WHO staff from the WHO Epidemiological Surveillance Centre in Nairobi undertook a carefully designed cluster sample survey. Approximately 2000 persons were examined in each of 5 different provinces. The results are shown in Table 19.8.

The vaccination coverage of individuals aged 5 years and over was satisfactory in the Central, Eastern and Coast Provinces but not in Western and Nyanza Provinces, in which the programme had first been launched and had been completed in 1970. In these latter two provinces, the vaccination coverage of children under 5 years of age was substantially

below expected levels; this was partly accounted for by the fact that health centres were vaccinating only about 25-30% of those born subsequent to the 1970 campaign.

At the conclusion of the campaign, in July 1972, 22 sectors were identified, to each of which a team with a vehicle was assigned. The teams were to proceed from one sublocation to the next, vaccinating those eligible for vaccination and inquiring at schools, markets and health units about possible cases that might have occurred during the preceding 3 months. Each team was expected to complete a tour of its sector once a year; in high-risk areas, the schedule was intensified to once every 3-6 months. The teams were called surveillance teams, but in fact their principal responsibility was to provide maintenance vaccination. The system remained in operation for little more than a year.

### Uganda

Like Kenya, Uganda had a reasonably extensive network of health centres and clinics and a complex of roads reputed to be the best in eastern Africa. A mass vaccination campaign using liquid vaccine was completed in 1966, following which the number of cases of smallpox diminished to only 365 in 1967 and 55 in 1968. Between 600 000 and 900 000 persons were being vaccinated annually in the various health establishments, and in 1969 freeze-dried vaccine supplied by WHO was introduced for use throughout the country. Because liquid vaccine had been employed in the previous vaccination campaign and because it was known that many of the vaccinations had not been successful, Uganda agreed in mid-1968 to undertake a special 3-year national vaccination campaign. WHO provided the necessary vehicles and equipment. However, the government later decided to abandon this schedule in order to conduct, in 1970, a national mass vaccination cam-

paing to be completed in just 6 months. To help to prepare the work, Dr Georgij Nikolaevskij, of the WHO Headquarters Smallpox Eradication unit, was detailed to Uganda for a 5-month period. He assisted Dr Yuriy Rikushin, a WHO medical officer originally assigned to Uganda for BCG vaccination. District health inspectors in each district organized the programme, which required the population to assemble for vaccination at collecting points. Vaccination staff were divided into groups of 3 or 4 persons who moved from subcounty to subcounty. In all, some 700 public health staff were engaged in the campaign. Between March and August 1970, 8.5 million vaccinations were performed in a population then estimated to be 9.8 million. There was no special assessment of the campaign to measure the prevalence of vaccination scars after it had been completed, but most believed that it had been generally well executed. Like the programme in Kenya, however, it was begun many months after smallpox transmission had been interrupted.

Following the campaign, vaccination continued to be performed by the various health centres in the country but only 100 000–200 000 persons were vaccinated annually, a figure equivalent to perhaps half the number of children born each year. In addition, sporadic campaigns which involved

the vaccination of about 100 000 persons were conducted in areas bordering on the Sudan following the importation of cases from that country.

Such knowledge as was available regarding the level of vaccinal immunity at the time was provided by 2 surveys carried out in different parts of northern Uganda (Table 19.9).

Both surveys were conducted in areas convenient of access by road, immediately after special area-wide mass campaigns had taken place. One must assume that vaccinal immunity in more remote areas of these districts and in other parts of Uganda was substantially below the levels shown in Table 19.9.

### Tanzania

Of the 5 countries, Tanzania was the only one which had expressed genuine enthusiasm about undertaking a programme. A thousand or more cases of smallpox had been reported almost every year since the 1950s, and in many outbreaks case-fatality rates of 5–10% had been recorded. Vaccination with liquid vaccine had been provided in health centres throughout the country, but no special programme had been conducted until 1965–1966, when the number of reported cases increased to 2762 in 1965 and to 3027 in 1966. During these 2 years, a mass campaign was conducted in which 6 million vaccinations were given and, subsequently, some 2–2.5 million vaccinations, with the low-potency liquid vaccine, were performed annually in health units, which then consisted of 105 hospitals, 54 rural health centres and 1442 dispensaries. However, 1629 cases were reported in 1967—and reporting in Tanzania was considered to be less complete than in Kenya or Uganda.

In August 1967, WHO and the government agreed on a plan of operations which provided for transport, equipment and sup-

plies of freeze-dried vaccine, as well as the assignment of a WHO medical officer, Dr Roger Lyonnet, and a technical officer, Mr D. G. Michalatos. The WHO staff arrived in the late spring of 1968, and in July 1968 a pilot project was begun in Geita District (population, 385 000) in northern Tanzania. This district had reported the highest incidence of smallpox of any in the country in 1966-1967 and was considered to be one of the most difficult in which to work because of poor roads and extensive swamps. During a 5-month period, a team of 24 vaccinators, a supervisor and 4 drivers performed vaccinations equal in number to more than 90% of the population.

Lack of government funds then resulted in the suspension of the campaign for 7 months, until July 1969, when it was resumed in the endemic north-western districts (see Fig. 19.2) and at the end of the year in 2 endemic south-eastern districts. Three mobile teams, each consisting of 23 persons, conducted the campaign under the direction of each area's district health inspector. The teams were subdivided into 4 units, each comprising a supervisor and 4 or 5 vaccinators and equipped with a motor vehicle, 2 bicycles and a kerosene-operated refrigerator. Political leaders, called "ten-cell chairmen," played an important role. Each was contacted one or two weeks before the team was due to arrive and was asked to prepare a list of all residents in the area for which he was responsible. When the team arrived, the residents were assembled and each was summoned by name for vaccination. The system might appear cumbersome and time-consuming, but in fact the vaccinators consistently averaged more than 500 vaccinations a day. They continued to achieve this norm even when, in 1970, they undertook the additional task of administering BCG vaccine to children under 15 years of age. The system was an unusual one but it worked well in Tanzania, in which the political structure was highly organized. An independent cluster sample survey conducted in Geita District by a team from the WHO Epidemiological Surveillance Centre in Nairobi revealed that 94% of the persons examined had vaccination scars at the conclusion of the programme (Table 19.10).

Later surveys, conducted during 1970 at the conclusion of campaigns in 6 regions, revealed comparable results (Table 19.11).

Although by the end of 1969 the vaccination campaign had been completed in only

1 district and had just begun in 3 others, the number of reported cases of smallpox that year decreased to 117. Reporting was still inadequate, since little had been done to improve the national reporting system; however, this was the lowest total of cases ever recorded. Even if the reporting system had not improved, it certainly did not appear to have deteriorated. Finally, in 1970, the investigation of some cases began. Of 3 outbreaks examined, 1 (in April) had resulted from an importation from neighbouring Zaire. Cases were reported from only 4 regions (Fig. 19.2), and in September the last case was found.

The programme continued, region by region and district by district, at length concluding with the vaccination of the population of the then capital, Dar es Salaam, in August 1973. While in most countries the residents of the capital city were the first to be vaccinated, they were left until last in Tanzania, since Dar es Salaam, situated on the coast, was far away from the known endemic areas. In all, 19.8 million persons were vaccinated against smallpox between 1967 and 1973 and 3.7 million under 15 years of age received BCG vaccine. After September 1970, vaccinators during their visits reported 23

**Plate 19.4.** Tanzanian posters in Swahili were widely distributed in 1969, reading: "This is smallpox. You and your family protect yourselves by getting vaccinated".

suspected cases but none proved to be smallpox.

On completion of the programme, mobile teams continued to vaccinate and to search for cases in remote and border areas; the health services vaccinated about a million persons each year thereafter but, as in Kenya and Uganda, interest in the programme diminished sharply.

### Rwanda and Burundi

The programmes in these densely populated countries, each with some 3.5 million inhabitants, were a study in contrasts. In both, the responsibility for operating the programme was largely delegated to their respective WHO smallpox advisers. One of these, Dr Celal Algan, was an energetic worker, well acquainted with conditions in the field, who, with the help of Rwandese staff, conducted one of the most effective programmes in Africa. The other, who was assigned to Burundi, rarely travelled to the field and had little apparent capacity for organization; the programme in Burundi reflected these shortcomings.

In both countries, the population lived in small hamlets and hillside villages scattered over a tropical and subtropical upland plateau. Roads were few and often impassable during the February–May rainy season. Hospitals, health centres and dispensaries, some operated by the government and some by missionaries or other private voluntary organizations, were comparatively numerous. In 1971 there were 157 hospitals, health centres and dispensaries in Rwanda and 104 hospitals and dispensaries in Burundi. Vaccination was offered at all these health units; about 10–15% of the population were vaccinated each year. The vaccine used was a liquid product which had been manufactured by a laboratory in Butare (Rwanda) since 1953. Beginning in 1965, this laboratory also produced some freeze-dried vaccine which, as has been mentioned earlier, was prepared in 600-dose vials. These vials contained such a large quantity of vaccine that it was often kept, unrefrigerated, for many days or even weeks, with a consequent loss of potency after the first day.

### Rwanda

Vaccination in Rwanda had been performed primarily by 2 teams, each consisting of 3 persons, who shared a vehicle and travelled regularly to 400 vaccination points established at health facilities and schools. A sample scar survey conducted in 1968 of 10 404 persons in 3 different prefectures showed a generally low level of vaccinal immunity, especially among children (Table 19.12).

An agreement was signed with WHO in April 1968 which provided for the assignment of a WHO medical officer and the supply of vehicles and equipment, vaccine and needles, as well as for the costs of petrol and vehicle maintenance to be met by WHO. However, at the end of 1968, the Ministry of

**Table 19.12.** Rwanda: results of vaccination scar surveys in 3 prefectures, by age group, 1968

Health and WHO staff working in the country re-evaluated the plan and decided to combine the field activities with those of a BCG vaccination campaign then under way. Dr Algan, at that time the WHO adviser for tuberculosis control in the country, volunteered to assume responsibility for both activities.

In mid-April 1969, the programme began operations with a supervisor and 10 vaccinators who worked in pairs, one administering BCG vaccine and the other

smallpox vaccine. Only a single vehicle was available, and so the team moved as a group to the various administrative units (prefectures), where vaccination was performed at collecting points. Areas from which cases were reported were attended to first. Hospitals and health clinics were supplied with vaccine and encouraged to participate in giving vaccinations.

As was the practice in other countries, Dr Algan and his Rwandan counterpart held meetings with local authorities beforehand to

**Plate 19.5.** **A:** Celal Algan (b. 1926), previously the WHO medical officer assigned to Rwanda for tuberculosis control, assumed responsibility in 1968 for organizing the smallpox eradication work in a campaign combining the administration of smallpox and BCG vaccines. The well-planned, rigorously supervised operation completed its 36-month work plan in half that time, while simultaneously developing an effective surveillance programme. Subsequently, as the WHO regional adviser on smallpox eradication in Africa (1975–1980), Algan organized the extensive activities required for the certification of eradication. **B:** Land Rovers move out for field work towing trailers with camping equipment. **C:** Rwandan vaccination team

explain the programme and to identify the most suitable collecting points and work out the best schedule. Local political leaders were given the responsibility for convening the people on the appropriate day and, later, for the reporting of smallpox cases. Concurrent assessment of the campaign was by random sample evaluation to ascertain take rates.

From the beginning, the team worked conscientiously and well, initially averaging 750 vaccinations per vaccinator per day and later as many as 1500 vaccinations per vaccinator per day. The productivity reported was in fact so high that the figures were viewed with scepticism by Ladnyi and WHO Headquarters staff. Ladnyi, however, confirmed the validity of the data during a special visit, noting in passing that the vaccinators complained only of sore fingers and wondered whether thimbles could be provided.

In October 1969, the vehicles intended for the programme were delivered and, with additional transport available, the complement of staff was increased to 27 (2 supervisors and 25 vaccinators, 5 of whom served as drivers); the personnel were divided into 3 teams, of which 2 were occupied with vaccination and the third, headed by Dr Algan,

with surveillance-containment. By the end of 1969, 989 000 persons had been vaccinated against smallpox by the mobile teams and 54 000 children had been given BCG vaccine.

During 1970, the investigation of 18 reported cases led to the discovery of 235 additional cases. After April, only 3 outbreaks, consisting of 3, 5 and 8 cases respectively, were discovered; each had resulted from importations from Zaire.

By the end of October 1970, only 18 months after the vaccination campaign began, the programme had been completed. During this period, the teams had vaccinated more than 3 million persons. A scar survey conducted in 1971 showed that, of those examined, 87% of children aged 0-4 years had vaccination scars, as did 97% of those aged 5-14 years and 93% of persons aged 15 years and over.

After the programme had been completed, hospitals and clinics continued to administer smallpox and BCG vaccines, while 8 teams, each consisting of 3 vaccinators, travelled throughout the more remote areas, especially those bordering Zaire, to search for cases and to vaccinate.

**Plate 19.6.** The recording form used in vaccination centres in Rwanda. The numbers of smallpox vaccinations and revaccinations administered could be quickly and easily noted by age group.

*Burundi*

Vaccination in Burundi had traditionally been performed by health units. In 1966, however, 500 000 persons were vaccinated during a special mass vaccination campaign undertaken after the occurrence of 1213 reported cases of what was said to have been variola minor. Sample surveys carried out by Ladnyi in 3 prefectures of Burundi in June 1968 revealed a remarkably high level of vaccinal immunity in all age groups in 2 of the areas in which the campaign had been conducted, and satisfactory levels in individuals aged 5 years and over in the third area (Table 19.13).

A plan of operations for an eradication programme was agreed on and signed in December 1967 by WHO and the government. How much smallpox might be present was unknown, since reporting was very incomplete. Only 74 cases were recorded in 1967, but the number rose to 301 in 1968.

In December 1968, a WHO medical officer arrived on assignment, along with supplies and equipment. Field activities began in May 1969 with 2 (later 4) mobile vaccination teams, each consisting of a supervisor, 4 vaccinators, an enumerator and a driver. The number of staff increased to 31 by mid-1969 and to 50 by 1971. The method of work was similar to that in Rwanda although never characterized by the same degree of careful planning and diligence. During 1969, only 415 705 vaccinations were performed, a number far lower than in Rwanda. Ladnyi, who visited the programme in February 1970, discovered that none of the vaccine was being kept under refrigeration, that vaccinators were issuing each vaccinee with a signed and officially stamped certificate of vaccination and that vehicle maintenance was virtually nil. The existing stocks of vaccine were destroyed and new supplies were flown in; the time-consuming practice of issuing individual certificates of vaccination was stopped; but a proposal to replace the WHO smallpox adviser was rejected. Fortunately, a new WHO country representative, Dr

Christos Karamustakis, arrived at this juncture. An intelligent, industrious person who had worked previously in Zaire and knew the smallpox programme there, he assumed on a part-time basis an overall supervisory role and, thereafter, the programme proceeded better. However, despite a far greater complement of personnel than in Rwanda, and despite the absence of the requirement for simultaneous administration of BCG vaccine, the mass vaccination campaign in Burundi took more than 2 years to complete and did not conclude until June 1971.

In all, 2 997 500 vaccinations were performed between 1969 and 1971. No concurrent assessment of coverage was performed, nor were vaccinations checked to find out whether they were successful. Following the campaign, vaccinal immunity was not high, as was revealed in a 1973 sample survey conducted by a team from the WHO Epidemiological Surveillance Centre in Nairobi (Table 19.14).

The local health services were expected to continue the vaccination campaign but little had been done to obtain their cooperation and thus the number of vaccinations performed in 1972 dropped to only 30 000. Other WHO staff were brought in to help to organize an effective reporting and maintenance vaccination programme, and by 1973 reporting had begun to improve and the number of vaccinations to increase.

**SMALLPOX OCCURRENCE, 1969-1970**

Only 355 cases were reported from the 5 countries in 1969 and 484 cases in 1970. How accurately this reflects the true incidence of

smallpox is difficult to assess. The eradication programmes consisted essentially of the traditional mass vaccination campaigns of the past, few of which incorporated either concurrent assessment of coverage or a special surveillance-containment element.

A national surveillance programme which served to ensure that all suspected cases were investigated and the outbreaks contained was a difficult concept for the countries to grasp and to implement. This was especially true of the former colonies of the United Kingdom, since their health services tended to be much more decentralized, the primary responsibility for health programmes being vested in district medical officers. This policy of decentralization of authority and responsibility offered many advantages in implementing a variety of programmes but not for the development of a national surveillance programme. District medical officers considered the control of smallpox to be specifically their own responsibility and resented the intrusion of a national presence. Where district medical officers were competent and diligent, this was not a problem; but many were not, and for all of them smallpox was but one of an array of problems and not always of high priority. A report of the occurrence of smallpox evoked the typical response that cases occurred in the province from time to time.

Ladnyi struggled to try to improve reporting and surveillance but, with responsibility for 19 countries, could devote little time to any single country. Moreover, he had been instructed by the regional office that he was not to undertake travel unless a visit was specifically approved in advance by the country and by the regional office, a process which he found to require at least 6 months. He ultimately decided to sidestep this restriction by sending a telex to the regional office informing it of his proposed travel plans and indicating that he would proceed unless instructed otherwise within the next 2-3 weeks. Rarely did the regional office reply in less than 4-8 weeks to any communication. A pattern therefore evolved in which Ladnyi proposed a trip and, receiving no reply, went ahead with his travel plans and eventually returned to Nairobi. After his return, he often received a telex advising him not to undertake the proposed trip.

In 1969, with so few cases being reported in eastern and southern Africa, it seemed that transmission would be interrupted quickly whatever the status of the vaccination cam-

paigns. Accordingly, on 4 June 1969, Henderson wrote to the regional office and to Ladnyi in the following terms:

"I believe that it is absolutely, vitally and unequivocally essential that provision be made for a responsible person, preferably a medical officer, to investigate personally each and every case to verify the diagnosis and to assist with or carry out himself the necessary investigations and containment activities. Any plan not incorporating this particular feature is doomed to failure . . . Experience throughout the world both in endemic and in non-endemic areas has clearly shown that when full responsibility is entrusted to the district health authorities, the results obtained are highly irregular and frequently unsatisfactory."

Interestingly, eastern Africa in particular was to disprove Henderson's sweeping prediction of failure. The status of smallpox in 1969 was anything but clear. Kenya ceased to detect cases that year. Burundi recorded 108 cases and Tanzania 117 cases, but in neither country was there an adequate surveillance programme. In Rwanda, on the other hand, efforts were made to improve reporting and to investigate outbreaks. There, Dr Algan sought to obtain reports from the health units and, when outbreaks were found, redirected the programme to conduct mass vaccination in the infected areas. Virtually all cases in Rwanda were those detected by the special teams. It is probable that reporting was also somewhat more complete in 1969 in Burundi and Tanzania because vaccination teams worked in infected areas and detected cases in the process. However, it is likewise probable that some of the reported cases were misdiagnosed cases of chickenpox. Uganda, for example, originally reported 19 cases in 1969, but when these were investigated by a WHO consultant, only 9 were found to have been smallpox.

In 1970, Kenya reported no cases and Uganda only 2; the latter, when investigated by a WHO consultant, were found to have been infected in the Sudan and Rwanda respectively. Tanzania detected only 32 cases, the last in September. Twenty-three of the cases occurred following an importation from Zaire; the others were not investigated. In Burundi vaccination teams found 197 cases, about which nothing more is known; the last of them occurred in October. Rwanda reported 253 cases in 1970, of which 18 were notified by the health services and the rest detected by the surveillance team. Transmis-

sion in Rwanda was interrupted in April 1970, although 3 outbreaks resulting from importations from Zaire occurred between August and October. Data regarding the age distribution of cases throughout 1969-1970 are available only from Rwanda (Table 19.15). Virtually all the cases were in children under 15 years of age, almost half of them under 5 years old.

Increased confidence that reporting was reasonably complete in 1970 was provided by the expanding vaccination campaigns, which served both to improve vaccinia immunity and to detect any cases that were present. In October 1970, the last cases were reported from these 5 countries, but not until nearly a year later could it be stated with confidence that transmission had actually been interrupted.

The rapid disappearance of smallpox from this area was surprising considering the perfunctory surveillance and containment activities. Levels of vaccinia immunity varied widely from place to place but, except where the systematic vaccination campaigns had been conducted, they were not generally high. Indeed, smallpox had disappeared from all but the densely populated areas of Burundi, Rwanda and Tanzania before the campaigns began. In retrospect, a combination of factors was probably responsible: (1) a generally scattered population with few large urban centres; (2) limited travel by most of the population, many of whom respected the numerous tribal boundaries; (3) prevalent, although not universal, tribal traditions which called for patients to be isolated in a separate hut and cared for by someone who had had smallpox; (4) a comparatively extensive network of health centres which, when freeze-dried vaccine was made available, successfully immunized a large proportion of people; and (5) the presence of a form of smallpox which spread less readily than did *variola major* in Asia and against which

successful vaccination provided a longer-term immunity.

After 1970, outbreaks were reported only in Kenya and Uganda, in the former following importations from Ethiopia and Somalia, and in the latter from the Sudan.

## IMPORTATIONS INTO UGANDA

It is probable that transmission in Uganda was interrupted in 1968. Only 9 cases were detected in 1969, and although the sources of these outbreaks were not clearly traced, 6 occurred in Sudanese refugee camps in its northern districts and the other 3 in the south among refugees from Rwanda. In 1970, 1 case occurred in the north in a refugee infected in the Sudan and 1 case in a person infected in Rwanda. During 1971-1972, Uganda recorded 35 cases, all in its northern districts among Sudanese refugees and members of the local population who were in contact with them. These are shown as imported cases in Table 19.1.

Juba Province in the southern Sudan lay just across Uganda's northern border and there a protracted civil war had been in progress. Tens of thousands of Sudanese refugees had taken up residence in northern Uganda and many continued to move back and forth between the two countries. The health services in Juba had been devastated by the war, vaccinia immunity was low, and, throughout 1972, smallpox was widely prevalent.

In October 1970, when Uganda had completed its mass vaccination campaign, it reverted to its previous pattern of operations, whereby vaccination was performed at clinics and health centres; district health inspectors assumed responsibility for surveillance activities and the containment of any outbreaks that were found. WHO recommended that a national surveillance team should be constituted to improve reporting and to participate in the investigation of any reported outbreaks, but this advice was not followed.

In 1971, 19 cases were reported from the northern districts of Acholi and Madi, 15 of which occurred in Sudanese immigrants; 4 local residents were infected by them. In 1972, 16 further cases were detected in this same area, primarily among Sudanese nationals. WHO staff who visited the area discovered that containment measures were not

promptly taken, the investigation of outbreaks was perfunctory, containment was poorly executed and a number of cases reported locally were not notified to the national authorities. Fortunately, in this sparsely settled, reasonably well vaccinated area, the spread of smallpox was even less efficient than the performance of the staff.

In early 1973, a special training programme in surveillance-containment was conducted for the staff in northern Uganda, and in April a central surveillance team was constituted to investigate all suspected cases. A number of suspected cases were competently investigated and specimens obtained, but none proved to be smallpox. Meanwhile, Uganda's only remaining endemic neighbours, Zaire and the Sudan, succeeded in interrupting transmission—Zaire in June 1971 and the Sudan in December 1972. Thus, the surveillance team began work in Uganda after the risk of importations had all but ceased, ironically paralleling the execution of its national vaccination campaign, which began after smallpox transmission had been interrupted.

### IMPORTATIONS INTO KENYA

Kenya, in contrast to Uganda, initially took more vigorous steps to improve reporting and established a national surveillance team in 1970. Six suspected cases were investigated in that year, all of which proved to be chickenpox. In March 1971, a nomadic herdsman from Ethiopia, travelling while ill, crossed the border and infected residents in a village some 70 kilometres south of the border. Subsequently 44 more cases occurred in 3 generations of transmission, 5 of the cases being fatal. The large proportion of deaths was unusual for outbreaks in the Kenya-Ethiopia area at this time, but whether the outbreak was due to *variola major* rather than *variola minor* is unknown. Mass vaccination had not yet been conducted in this area but, because of the outbreak, teams were quickly transferred to the district. Six thousand persons were vaccinated in and around the village, and the teams subsequently searched and vaccinated the entire district. No further cases were discovered.

In April 1971, another case was reported from a village 150 kilometres east of the first (Fig. 19.4). The patient was an Ethiopian adult visitor who resided just 14 kilometres

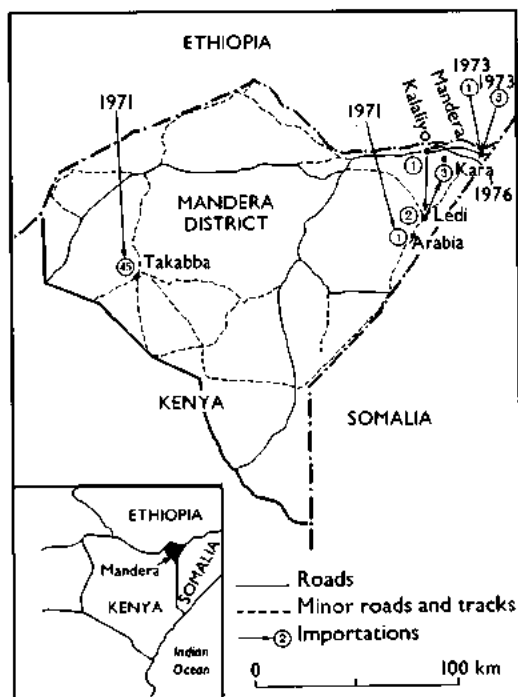

Fig. 19.4. Kenya: sources of importations of smallpox, 1971-1976.

north of the border. More than 95% of the village people had already been vaccinated and no further cases occurred.

The national mass vaccination campaign concluded in June 1972 and, at that time, the country was divided into 22 sectors, each with a mobile surveillance team which was supposed to be responsible for surveillance and for the vaccination of nomadic and other groups considered likely to import smallpox. By then, Ethiopia was Kenya's only neighbour with endemic smallpox.

In Kenya the surveillance programme proved to be little better than in the other countries. In part, this can be ascribed to the fact that no surveillance teams had been established before transmission was interrupted, and thus they had no experience either in the investigation or in the containment of outbreaks. Moreover, the absence of cases understandably led to complacency. Sustaining interest in smallpox eradication after transmission had apparently been interrupted was difficult in all countries and especially difficult in Kenya. Following the outbreaks in March and April 1971, no further cases were detected for more than 2½ years.

On 30 December 1973, a 25-year-old man with smallpox was found in Mandera in north-east Kenya at the border with Ethiopia and Somalia. He had travelled 150 kilometres from an area in Ethiopia in which smallpox was known to be occurring. Containment vaccination was begun, and during the campaign a second case was discovered. The patient was a 23-year-old woman, who developed rash on 27 January and subsequently infected 2 other people. She had arrived in Mandera only 2 days before becoming ill and thus represented a second importation. The source was said to be a Kenyan village near the Ethiopian border, some 80 kilometres to the west. The fact that no investigation of this area was undertaken (although no further cases were reported) is indicative of the quality of the surveillance.

Again, 2 years were to elapse without cases. Meanwhile, Ethiopia reported its last cases in August 1976. In late September, however, Somalia reported its first cases for almost 2 years, in the capital, Mogadishu, supposedly resulting from importations from Ethiopia. As at the end of December, 39 cases had been reported, all in Mogadishu (see Chapter 22). When the report of cases in Somalia was received, a Kenyan team was sent to the border area to undertake an active search for cases. This team then represented virtually the only surveillance unit within 150 kilometres or more, since because of fighting in the area, Ethiopian teams had to remain at least that distance from the Kenyan border. Somali staff, if they were finding cases outside Mogadishu, were not reporting them.

That smallpox did not spread into Kenya must be attributed more to good fortune and to a sparse population than to the work of the inexperienced surveillance team. In December 1976, smallpox was again introduced into Mandera District (see Fig. 19.4). From the available, and somewhat conflicting, reports, it appears that a 40-year-old Kenyan man, who had been studying in an Islamic school near Mogadishu, became ill with smallpox on 26 December. He was then staying with his brother in a village, Kalaliyo, 29 kilometres west of Mandera town; 3 days later, he travelled some 35 kilometres south to a village, Ledi, to stay with his sister, and soon thereafter he returned to Somalia. The health officer in Mandera, informed that a case resembling smallpox had been seen in Ledi, sent a health inspector and a vaccinator. On arrival, they were told that the patient had

left; they returned without vaccinating anyone. On 13 January 1977, a subchief reported that the patient's sister had developed a rash. This time, the surveillance team went to Ledi, obtained a specimen and departed. Eleven days later, a report was received from a Nairobi laboratory that the specimen contained smallpox virus. On 26 January, the team again went to Ledi and found that the family had departed for a village (Kara) some 50 kilometres to the north-east. Another day elapsed before they could be found. Vaccination was then begun but 2 daughters became ill with smallpox on 22 and 27 January and another daughter (still unvaccinated) on 7 February. The patients were advised to stay in the house, but it was learned later that the mother regularly left the house to obtain water from a nearby water-hole frequented by a number of people.

Additional staff were sent from Nairobi to assist, and on 17 February 1977 WHO epidemiologists well acquainted with surveillance and outbreak investigation arrived. Mass vaccination carried out by 6 teams with vehicles in villages and towns accessible by road had commenced on 28 January. By mid-February, the proportion of the population vaccinated reached 80% in the main villages, but only 30% in more remote villages. In fact, the 16 inhabitants of a village located just 2 kilometres from the outbreak were found, in early March, not to have been vaccinated at all. Meanwhile, because of heavy rains in the area, many nomads began moving through the area from Ethiopia as well as Somalia. At the end of April, a survey of 2256 persons in a nearby division revealed that only 527 (23%) had vaccination scars. By the end of February, a search had been organized throughout the eastern part of Mandera District which, by assessment, was reasonably effective. A reward of 200 Kenya shillings (US\$24) was offered to anyone reporting a case. Gradually, monthly searches were extended to other districts bordering on Ethiopia and Somalia, but because of mud, vehicle breakdowns and scarcity of staff, probably not more than a half to two-thirds of the districts were satisfactorily searched. The searches continued until March 1978, some 6 months after the last known case occurred in Somalia.

It was feared that more cases would be found, but only 1 additional case was discovered by the search teams, in a 25-year-old man who had become ill on 16 December 1976. The source of infection was not

BY COURTESY OF Z. ISLAM, 1977

**Plate 19.7.** The strategy for search activities in Kenya during 1977 was worked out by Jean-Paul Ryst (b. 1939), a WHO consultant, Ziaul Islam (b. 1931), a WHO medical officer for epidemiological surveillance in Africa, 1971–1982, and Wilfred Koinange (b. 1939), Director of Health Services of Kenya.

determined although it was considered to be unrelated to this outbreak. Meanwhile, efforts were made to find the original case in Somalia but it was never discovered.

### CONCLUSION

The circumstances attendant on the eradication of smallpox from these 5 countries were wholly unlike those encountered in Asia or South America. In Asia, levels of vaccinal immunity comparable with, and in many instances better than, the levels observed in eastern Africa failed to stop transmission. Only when a fully effective surveillance–containment programme was introduced could transmission be interrupted. In Brazil, surveillance and containment played a notably less important role in eradication, but there the vaccination campaign was carefully executed with specially trained assessment teams evaluating the performance of the vaccination teams on a daily basis. In Kenya, Uganda, and Tanzania, smallpox incidence was diminishing rapidly by the time the Intensified Programme began. In all but limited areas of Tanzania, and in Rwanda and Burundi, the introduction of freeze-dried vaccine of good quality was all that was required to interrupt transmission; the extensive infrastructure of health services did the rest. Mass vaccination campaigns, with neither assessment nor surveillance (except in

Rwanda), served to eliminate smallpox in the other areas.

Whatever the deficiencies of the programmes, smallpox transmission was rapidly interrupted at little cost, with the addition of only a few experienced health staff, a small cadre of minimally trained vaccinators and encouragement and support from WHO. In retrospect, many factors account for this success: the substitution of freeze-dried for liquid vaccine; the ready, even enthusiastic, acceptance of vaccination by most of the population; the good cooperation of village leaders, missionaries, teachers and others; the presence of milder strains of variola virus which spread less easily; the generally sparse population and the infrequency with which they travelled over long distances; and an extensive network of health centres and clinics, many of which undertook to control outbreaks when these were discovered.

Of particular note in these countries was the extraordinarily high productivity of the staff compared, for example, with that of their counterparts in the Indian subcontinent. Whereas in the latter group of countries, the performance of 25 vaccinations by a vaccinator in one day was considered to be a worthy accomplishment, African vaccinators regularly vaccinated on average 500 or more individuals a day, the record being achieved in Rwanda, where during a particular month,

the vaccinators, using bifurcated needles, averaged 1508 vaccinations per vaccinator per day. In the Indian subcontinent, it was considered necessary to have at least 1 smallpox vaccinator for every 5000-8000 or 20 000 persons, according to circumstances. In the countries of eastern Africa, on the other hand, the total smallpox eradication staff, at maximum strength, numbered only 1 per 148 000 persons in Kenya, 1 per 180 000 in Tanzania and 1 per 136 000 in Rwanda.

The rapidity with which success was achieved in these and other African countries, at such little cost and with minimum effort, provided enormous encouragement to the global eradication programme. To have interrupted transmission in countries in which health services were considered to be less effective and extensive than in Asia was an important factor in motivating Asian governments to make a more concerted attack on the problem.

### INTRODUCTION

In southern Africa, 10 countries or political jurisdictions lie south of Zaire and the United Republic of Tanzania, occupying an area of 6 million square kilometres (Fig. 20.1). This land mass consists principally of a great central plateau, primarily temperate to sub-tropical in climate; in 1970 its estimated population amounted to 54 million. The vast deserts of the Namib and Kalahari in the west encompass much of Namibia and Botswana, giving way to undulating plains and savanna to the east and eventually to detached groups of hills and mountains which extend from Malawi through western Mozambique and eastern Zimbabwe (called Southern Rhodesia prior to 1980).

In 1967, when the Intensified Smallpox Eradication Programme began, smallpox throughout southern Africa did not appear to be a major problem. Four areas—Angola, Botswana, Lesotho and Namibia—were believed to be non-endemic; 6 other areas recorded a total of only 534 cases in 1966 and 262 in 1967. Health services in most parts of southern Africa were generally more extensive than elsewhere in the continent and all

had some type of organized programme of smallpox vaccination. Although smallpox was undoubtedly a greater problem than official data conveyed, it was thought to be not as widespread or of such high incidence as in neighbouring Zaire or the United Republic of Tanzania, for example.

Given the status of smallpox and the national resources available in many of the countries, prospects for the early interruption of smallpox transmission throughout this vast area might have appeared hopeful. However, political problems made it difficult for WHO to cooperate with the authorities in large parts of southern Africa, and these constraints inhibited the programme. Only 4 countries, with a total population of 10.4 million (in 1970), were Member States of WHO with full voting rights (Table 20.1). A fifth, Swaziland, became independent in 1968 and joined WHO a few years later. Official contact between the Organization and the health authorities of the other 5 political jurisdictions, which had a total population (in 1970) of 42.8 million, was difficult at best and in certain cases practically nonexistent. Angola and Mozambique, both Overseas Provinces of Portugal until 1975, were preoccupied with a

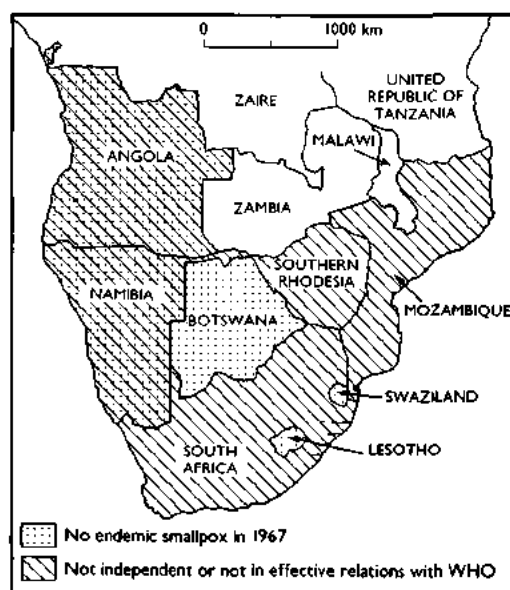

Fig. 20.1. Southern Africa: countries and territories, smallpox endemicity, and relationship with WHO, 1967. The endemicity shown reflects the situation in 1967 as determined later.

protracted and costly civil war. Contact with their health authorities had to be made through the government in Lisbon, for which smallpox eradication was an issue of little significance compared with other problems. Namibia (South West Africa) was administered by South Africa, which, though still a WHO Member State, had been deprived of voting privileges and services by the Seventeenth World Health Assembly in 1964 and which had subsequently ceased to pay its annual contribution or to attend the World Health Assembly. Communications between WHO and South Africa all but ceased at this time, along with South Africa's participation in the Organization's activities. Until 1965, Southern Rhodesia had been an Associate Member of WHO, being represented by the United Kingdom in its international relations. When the government unilaterally declared independence, its rights were suspended on the initiative of the United Kingdom. Communications between WHO and Southern Rhodesia had officially to be conducted through the government in London, but there was little or no official contact between the United Kingdom and the new government of Southern Rhodesia.

The only permissible contact between WHO and the 5 above-mentioned political

jurisdictions was embodied in the provisions of the International Health Regulations, which required each to report weekly to WHO Headquarters the number of cases of smallpox, as well as other stipulated "quarantinable diseases", and the areas that were affected. WHO Headquarters, in turn, could query reports and transmit information deemed to be of importance in the control of these diseases. Although many of the authorities concerned, like those of some other countries, were neither prompt nor comprehensive in their reporting, this contact, tenuous as it was, proved to be an important one.

A further difficulty lay in the fact that smallpox eradication held little interest for South Africa, in which an especially mild form of variola minor was prevalent, the severity of which was comparable to that of chickenpox.

In the circumstances, WHO could freely communicate with and provide assistance only to its "active" Member States, which together accounted for just 20% of the population of southern Africa. It was hoped that in the other endemic areas, programmes would eventually be conducted, if for no other reason than to avoid opprobrium in the eyes of independent African governments which had succeeded in eradicating smallpox.

It was therefore difficult to assess the extent of endemic smallpox in most countries of southern Africa between 1967 and 1971, not only because of problems of communication

<sup>a</sup> Deprived of voting privileges and services in 1964.

but also because the completeness of notification improved only slowly during this period. Few outbreaks in any country were investigated by appropriately trained staff or were confirmed by laboratory diagnosis. As a consequence, the extent of underreporting, the numbers of reported cases and outbreaks that represented importations from other countries, and the numbers of cases of chickenpox that might have been misdiagnosed as smallpox were, and remain, a matter of conjecture.

Mass vaccination campaigns, assisted by WHO, were conducted in Botswana, Malawi and Zambia; similar campaigns, assisted by WHO and UNICEF, were carried out in Lesotho and Swaziland. None, except the Botswana campaign, was particularly well executed. Nevertheless, transmission was interrupted in Zambia in 1968 and in Swaziland in 1966 or 1969, as is discussed later in this chapter. In Malawi, the disease disappeared in 1971. Lesotho's last cases had occurred in 1962, 5 years before the beginning of the Intensified Programme.

Of the 5 political jurisdictions in southern Africa referred to earlier, Angola and Namibia remained smallpox-free, but endemic smallpox was present in 1967 in the other 3—Mozambique, South Africa and Southern Rhodesia. Because of political constraints, they received no help from WHO in their programmes. Mozambique conducted an extensive vaccination campaign in areas accessible to the health authorities, and in February 1969 the last cases were detected. Southern Rhodesia recorded small numbers of cases throughout 1970, all of them along its eastern border with Mozambique. The last known case occurred in December 1970, but whether it was the last in a continuing chain of endemic transmission or a result of importations from remote areas of Mozambique or Malawi remains unknown. South Africa began active eradication measures in 1970, conducting extensive systematic vaccination campaigns in northern parts of Transvaal Province, its only known endemic area. In 1971, it recorded its last indigenous case.

From February to August 1971, no cases of smallpox were reported to WHO from any country in southern Africa. Just when hope was growing that smallpox had been eliminated from this large area, cases began to be reported from Botswana, a hitherto smallpox-free country, adjacent to South Africa's Transvaal Province. During the

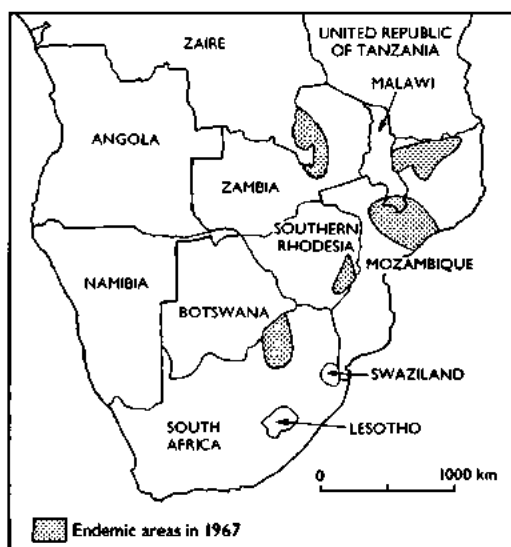

Fig. 20.2. Southern Africa: probable extent of endemic smallpox, 1967.

preceding 6 years, only a single imported case had been detected in Botswana. Vaccinal immunity throughout the country was low and smallpox began to spread. This was alarming. Not only might smallpox again become established in a country that had been free from it, but it was feared that it might spread through the populated areas in north-western Botswana into areas of Angola which were inaccessible because of civil war. If smallpox were to become re-established there, the prospects for eradication would be significantly diminished. Effective measures to control the disease were greatly delayed but, by good fortune, it remained confined to Botswana, in which more than 1000 cases were recorded during 1972 and transmission persisted until November 1973.

On the basis of a retrospective review of data collected during the course of the programme and, subsequently, during activities leading to certification, it is probable that in 1967 there were not more than 5 comparatively small foci of smallpox (Fig. 20.2). One was in Zambia in areas adjacent to the then heavily endemic Katanga (Shaba) Province of Zaire. A second straddled the Mozambique–United Republic of Tanzania border, where a Mozambican independence movement was centred and where military forces associated with this movement, as well as refugees, moved into and out of the United Republic of Tanzania. A third lay in central

Mozambique and southern Malawi, likewise an area in which security was a problem; a fourth was in rural mountainous areas of Southern Rhodesia and may or may not have extended into adjacent areas of Mozambique; the fifth was in Transvaal Province of South Africa. In all areas except South Africa, smallpox with a case-fatality rate of 5–15% prevailed; in South Africa, a very mild form of variola minor was present with a case-fatality rate of less than 1%.

In this sparsely populated region of Africa, smallpox was readily interrupted with national or regional mass vaccination campaigns, few of which are believed to have achieved the high levels of vaccinia immunity attained in Zaire and western Africa. Moreover, except in Botswana, programmes of surveillance and containment were never well developed. However, the eradication programme served in some countries to develop reporting systems and to promote routine vaccination against this and other diseases in existing health facilities. It is apparent in retrospect, though, that eradication might have been achieved more readily and more rapidly if freeze-dried vaccine had been supplied to existing health programmes and if simple surveillance activities had been developed.

This chapter discusses first the activities in Zambia and then the programmes in Malawi, Mozambique and Southern Rhodesia. A third section deals with smallpox in the adjacent

countries of South Africa, Botswana, Lesotho, Namibia and Swaziland. Lastly, activities in smallpox-free Angola are briefly described.

## ZAMBIA

Zambia, a subtropical country consisting largely of wooded plateau, became independent in 1964. Its population of 3.8 million (in 1967) lived primarily in scattered villages, only 700 000 being resident in the 9 major towns. Its road system was comparatively extensive, as was its network of health facilities, which included 60 hospitals, 93 urban and specialized clinics and 323 rural clinics. Many of these were staffed by expatriates, there being at that time only 3 Zambian physicians and a dearth of Zambian paramedical staff. Few of these health units, however, provided vaccination against smallpox.

Smallpox, with a case-fatality rate of 5–15%, similar to the form existing in neighbouring Zaire, had been prevalent for many years (Table 20.2). Mass vaccination campaigns employing liquid vaccine were conducted during periodic outbreaks.

In 1963–1964, major epidemics began to occur in Zambia (Fig. 20.3), primarily along the Zairian border. The new government responded with a national mass smallpox vaccination campaign utilizing specially con-

stituted mobile teams. The programme began in 1964 in each of 8 provinces under the supervision of provincial officials. One hundred and forty vaccinators were recruited and trained locally and discharged when the team had completed its work in a given area. They vaccinated at assembly points, using liquid vaccine. The intent was to vaccinate one-third of the population of each province each year. Vaccinations were performed during the dry season, from May to November. Despite a serious shortage of transport, limited supervision and inadequate refrigeration facilities, 1.66 million vaccinations were reported to have been given during 1964 and 1.5 million in 1965. Take rates among primary vaccinees were found to be about 80%. This was lower than the take rates expected when freeze-dried vaccine was used but, considering the logistic problems in the country, it was a remarkably good result. The number of reported cases decreased sharply, from 2214 in 1964 to 528 in 1965.

In January 1966, freeze-dried vaccine, donated by the USSR, began to be employed. That year, another 1.54 million persons were vaccinated, and the number of cases decreased further to only 63 in 1966.

The government was committed to smallpox eradication and in March 1967 requested WHO to provide vehicles, refrigerators and other equipment as well as 4 advisers—a medical officer counterpart for the director and 3 operations officers to serve in supervisory roles, where needed, at provincial level. Between 1967 and 1973, WHO was to provide 10.6 million doses of vaccine and expend US\$644 146, an outlay which included WHO salary payments. The WHO medical officer arrived in November 1967 and the 3 operations officers in 1968. Meanwhile, the government staff for the mass vaccination campaign was increased from 140 to 207.

Under the new WHO-assisted programme, BCG vaccine was given simultaneously to all schoolchildren and, in two of the provinces, to younger children as well. Between January 1966 and the end of 1968, the so-called "first phase" of the programme was completed—i.e., vaccination with freeze-dried vaccine throughout the country. The number vaccinated was roughly equivalent to the estimated population. In 1968, only 33 cases were reported and smallpox transmission appears to have been interrupted in December of that year.

During 1967–1968, the WHO-assisted programme changed little in character. Vaccination was conducted at assembly points; coverage and take rates were assessed only occasionally; little was done to improve the surveillance system. Indicative of the quality of surveillance is the fact that little is known about the last 10 cases reported in 1968, except that 2 were said to have been infected in Zaire.

Beginning in 1968, the established government health units were provided with stocks of vaccine and encouraged to vaccinate all who attended but, as was true in many countries, these units evinced little interest in undertaking even this most simple of preventive measures. Throughout the whole of 1969, they performed only 91 650 vaccinations and many of these were given by programme vaccinators who were assigned to clinics. Fully 3 additional years of concerted effort were required before the staff of the health units began to vaccinate significant numbers of persons.

Although a programme of vaccination had been completed throughout the country, the government decided in 1969 to repeat the national mass vaccination campaign, using special teams as before. Because smallpox was still endemic in neighbouring Zaire, the United Republic of Tanzania and Mozambique and because the existing health units were providing little help, government officials felt that this was the only way that they could ensure a sufficiently high level of vaccinia immunity to prevent spread should introductions occur.

The WHO operations officers were assigned to the provinces bordering on Zaire, and vaccination check-points were established at the principal border crossings to examine persons entering the country and to vaccinate anyone without a scar. In some areas, the coverage achieved was assessed by WHO operations officers after the teams had worked in an area. Throughout Zambia, however, supervision generally remained poor, which was reflected in the unsatisfactory performance of vaccinators, who averaged only 40 vaccinations per day.

The repeat mass vaccination campaign was costly but it did assure the movement throughout the countryside of vaccination teams which could detect any cases that existed. Between 1969 and 1971, an additional 4.6 million vaccinations were performed, the annual average being no more than had been

achieved in 1964–1965, before the provision of WHO assistance.

During 1970, at the midpoint of this repeat round of mass vaccination, a cluster sample survey of the country was carried out by staff of the WHO Epidemiological Surveillance Centre in Nairobi, Kenya, to measure the level of vaccination coverage. In all, 17 927 persons were examined. The proportion with vaccination scars was found to range from 62% to 80% in the different provinces, but in 5 of the 44 districts it was discovered that fewer than 60% of the people had ever been vaccinated. By any standard, the programme had not been notably successful.

The need to recruit at least one experienced team to encourage reporting and to investigate each suspected case had been stressed repeatedly by Ladnyi, the WHO intercountry smallpox adviser for eastern and southern Africa, but not until late 1969 was such a team formed and the first efforts made to ensure that each of the 429 health units provided a weekly report. Even then, the effort left much to be desired: as late as June 1970 the WHO medical adviser to the national programme commented that a report of a suspected case was *usually* followed by immediate investigation. The concept that *every* suspected case was important was not understood.

Meanwhile, in Zaire, mass vaccination throughout the neighbouring Shaba Province was completed during 1969, although a few cases of smallpox were reported each month in early 1971. Despite the continuing presence of endemic smallpox just across the border, only 2 imported cases were detected in Zambia, in April 1970. These cases actually spent less than a day in the country. The individuals concerned—a 4-year-old child and a 7-year-old child—were brought across the river from Zaire by their parents to be examined at a clinic. They were diagnosed as suffering from smallpox by the staff of the clinic and were promptly sent back to Zaire,

but the incident was duly reported to the provincial health office. These were Zambia's last known cases.

Not until the beginning of 1971, when the risk of importations seemed to have diminished almost to nil, was a comprehensive surveillance system finally established in northern Zambia, near the borders with Zaire and the United Republic of Tanzania. In these areas each village was visited twice monthly by a surveillance agent to detect cases with rash and fever which might be smallpox. Additional permanent vaccination posts were established along the frontiers and many suspected cases were investigated. Because the United Republic of Tanzania detected no cases in 1971 and Zaire found none after June of that year, it is not surprising that no further cases were discovered in the bordering areas of Zambia.

With the conclusion of the second round of mass vaccination, the number of staff was reduced and the number of WHO advisers decreased from 4 to 2. A maintenance programme was established whereby 15 mobile vaccination teams moved through the provinces vaccinating the more remote populations and encouraging vaccination in established health facilities. In all, 1.4 million persons were vaccinated in 1972 and 1.5 million in 1973, numbers comparable to those vaccinated by the much larger special vaccination campaign staff. In the mid-1970s, immunization against several diseases began to be offered by many of the established health units, and monthly reports giving the number of cases of disease and the number of vaccinations performed were received regularly from 96 hospitals and 689 health centres and subcentres.

The age distribution of cases during 1964–1965 was unusual in that 86% of those recorded were in individuals aged less than 6 years (Table 20.3). This was an unusually high proportion of cases among young children,

Table 20.3. Zambia: age distribution of reported cases of smallpox, 1964–1965 and 1966–1968

1964–1965			1966–1968		
Age group (years)	Number of cases	%	Age group (years)	Number of cases	%
<1	626	23	<1	40	28

Total	2 742	100	Total	143	100

for which there is no explanation other than that it may have been an artefact of reporting. Data for the 1966-1968 period show a more typical age distribution of cases.

## MALAWI, MOZAMBIQUE AND SOUTHERN RHODESIA

### Background

Malawi, Mozambique and Southern Rhodesia together had a population of 18 million (in 1970) and a reasonably extensive network of health centres and roads, Southern Rhodesia's being the most fully developed. From 1963, the prevalent form of smallpox in these countries appears to have been variola major, with a case-fatality rate of 5-15%. During the early 1960s, smallpox had been of special concern to the health authorities, and all had organized mass vaccination campaigns employing mobile teams. Reasonably satisfactory control seems to have been achieved. In all, only 142 cases were reported in 1966 and 172 in 1967, although the true numbers were undoubtedly much greater because notifications in these countries, as elsewhere, were very incomplete.

The recurrence of variola major was a recent development. Variola major had been prevalent before 1952, but in that year it was replaced by variola minor. From 1952 to 1958, for example, Malawi recorded 810 cases but only 8 deaths. In 1959, both the number of cases and the case-fatality rate began to

increase and by 1961, 1465 cases with 161 deaths were reported (Table 20.4). The source of the strain which infected Malawi was in all likelihood either neighbouring Zambia or the United Republic of Tanzania. In Mozambique, a similar change in the prevalent smallpox strain took place in 1962-1964, at the time of civil conflict along its border with the United Republic of Tanzania. In 1963, fatal cases began to be observed in Southern Rhodesia, virtually all of them occurring in the eastern provinces bordering on Mozambique.

The civil war in Mozambique played a significant role in the persistence of smallpox in these countries. A national independence movement, which had been established in border areas in the south of the United Republic of Tanzania, moved into the 2 northern provinces of Mozambique in 1964. In addition to conducting guerrilla warfare, the independence movement established a political and administrative structure which, during the following decade, expanded into the central and north-western provinces. To combat this movement, the Mozambican government resettled many of the scattered rural population into villages which could be defended and in which health and educational services could be provided. Thus, village health units capable of reporting cases of smallpox existed throughout the country, but few activities were possible in the sparsely populated rural areas, including extensive tracts adjacent to the United Republic of Tanzania, Malawi and Southern Rhodesia.

Table 20.4. Malawi, Mozambique and Southern Rhodesia: number of reported cases of and deaths from smallpox and case-fatality rates, 1959-1972

<sup>b</sup> Nine cases documented during 1972 survey and 1 during 1977 survey.

### Vaccination Campaigns

For a number of years prior to 1967, a considerable proportion of the population in each country was reported to have been vaccinated each year (Table 20.5), but none of the programmes incorporated a system for assessing the level of coverage achieved, and only in Southern Rhodesia were take rates regularly appraised.

Freeze-dried vaccine was used only in Mozambique, the vaccine having been produced at the Instituto de Investigação in Lourenço Marques (now Maputo). Samples of this vaccine were tested by the International Reference Centre for Smallpox Vaccine in Bilthoven, Netherlands, in 1968 and 1972 and found to meet WHO standards. Vaccination in Mozambique was offered in hospitals as well as in health and first-aid posts and by mobile teams, each of 9 districts having 3 or 4 teams which sought to vaccinate one-third of the population each year. BCG vaccination was given simultaneously. During 1968, a special campaign was conducted which succeeded in vaccinating against smallpox half of the 8 million residents, although, because of security problems, 2 districts in the north, Niassa and Tete, could not be well covered. A repeat campaign was conducted in 1972, during which, because hostilities had subsided in Tete District, it was possible to vaccinate most of the people in this area. Although the coverage was not assessed, vaccinal immunity was probably reasonably good among accessible populations, considering that a large number of people had been vaccinated and freeze-dried vaccine had been used. However, immunity was undoubtedly much lower among the inhabitants of the

large sparsely populated rural areas of the central and northern parts of the country.

In Southern Rhodesia, a similar type of programme was conducted, with vaccination being given by mobile teams and in existing health facilities. Poliomyelitis and BCG vaccines were administered simultaneously to children. Until 1970, liquid smallpox vaccine produced in South Africa had been employed. A continuing assessment of take rates among primary vaccinees was conducted by local health authorities, and these showed 75–90% successful vaccinations—rates which were lower than those obtained with freeze-dried vaccine, but higher than those in most countries that used liquid vaccine. The only available data regarding the prevalence of vaccinal immunity are from a 1978 government survey, which found that 74% of children aged 1–6 years and 92% of those aged 7–10 years had vaccination scars.

In Malawi, a permanent staff of 42 vaccinators regularly travelled by bicycle through their assigned regions, giving smallpox vaccine only; a 10-man mobile team was available for vaccination where outbreaks occurred. The mobile team worked primarily in the south, where, after 1965, almost all cases were found. Until 1966, liquid vaccine was employed; primary take rates, when measured in the field, were only 25–50%. The programme was not particularly successful, as was apparent from a survey in 1965, which showed that only 360 of 2566 schoolchildren (14%) in and around the capital city had vaccination scars. In January 1966, freeze-dried vaccine was made available by UNICEF and thereafter only this type of vaccine was employed. WHO staff visiting the country in 1966 and 1968 found that the supervision of vaccinators was poor, their productivity was low and the vaccinal immunity of the population was unsatisfactory. In one area of southern Malawi, in which United States Peace Corps volunteers assisted in mass vaccination in 1968, 50% of the inhabitants remained unvaccinated at the end of the campaign. Late in 1969, the government decided to request assistance from WHO in conducting a national smallpox eradication programme, but a better-organized vaccination campaign did not begin until April 1972. That programme included the administration of both BCG and smallpox vaccines. When the campaign was launched, surveys in different areas showed that 30–60% of children aged 0–4 years and 36–76% of those aged

Table 20.5. Malawi, Mozambique and Southern Rhodesia: number of reported vaccinations performed, 1964–1973

Year	Number of vaccinations (% of total population)		
	Malawi	Mozambique	Southern Rhodesia
1964	569 000 (40)	1 056 726 (15)	2 495 112 (59)
1965	751 413 (19)	2 139 489 (29)	1 371 600 (31)
1966	832 201 (20)	1 463 938 (20)	1 109 997 (24)
1967	675 390 (16)	2 433 705 (32)	1 173 216 (25)
1968	768 000 (18)	4 111 960 (53)	1 144 930 (23)
1969	970 161 (22)	977 281 (12)	977 073 (19)
1970	1 265 335 (28)	1 234 986 (15)	1 198 282 (23)
1971	525 329 (11)	2 195 546 (26)	1 399 552 (26)
1972	562 347 (12)	2 379 761 (27)	1 401 168 (25)
1973	489 111 (10)	2 533 968 (28)	1 119 614 (19)

5-14 years had vaccination scars. Only 5 months after the programme had begun, it was stopped by the government on account of the occurrence of abscesses due to BCG vaccination. It did not recommence until August 1973—almost a year later—but was halted once again, in December 1973, when cholera broke out and the teams were re-assigned to perform cholera vaccination.

Finally, in 1974, an extensive vaccination campaign began, long after the last cases had been detected. It concluded in 1976. WHO financial support throughout the course of the programme amounted to US\$311 011; in addition, 7.8 million doses of vaccine were supplied.

### The Smallpox Situation

In the 3 countries under review, information about smallpox, from 1967 until 1971, when the last known cases were detected, is

Fig. 20.4. Malawi, Mozambique, Southern Rhodesia: number of reported cases of smallpox, by year, 1961-1972.

sketchy. Undoubtedly, many cases occurred which were not reported and some which were reported may not have been smallpox. Health authorities at district or provincial level in each country usually performed area-wide vaccination when cases were reported but rarely did they conduct investigations to detect additional cases or to identify the source of infection. Ladnyi, during visits to Malawi, tried to persuade the government to initiate a surveillance programme, but not until 1973 was a satisfactory programme established for the investigation of suspected cases of smallpox. Since there could be no direct official communication between WHO and the health authorities in Mozambique and Southern Rhodesia, a similar effort to encourage proper surveillance in these areas was greatly delayed. At the end of 1969, some WHO staff began corresponding personally with university faculty members in Salisbury, Southern Rhodesia, who soon thereafter undertook to examine specimens from many suspected cases although few epidemiological investigations were conducted. Not until the spring of 1972 did WHO and the countries concerned reach agreement to give Henderson special permission to visit Mozambique (as well as Angola and South Africa although not Southern Rhodesia) to assess the nature of their programmes and to discuss needed surveillance measures in areas then believed to be smallpox-free. Information about smallpox, even that pertaining to the last outbreaks, is thus fragmentary in all the countries concerned.

Mozambique detected 104 cases in 1967, 145 in 1968 and 11 in 1969 (the last occurring in February) (Fig. 20.4). Of the 145 cases in 1968, 142 were reported from parts of only 3 provinces, all in the north of the country (Fig. 20.5). Most of the outbreaks occurred in villages in Tete District, near the border with Malawi, and in Niassa District, which adjoined endemic areas in the United Republic of Tanzania. The 11 cases detected in 1969 were all in Niassa District. Because the guerrilla forces of the independence movement continued to travel between Niassa and the southern part of the United Republic of Tanzania, it is possible that these foci were related. This is speculation, however, since in neither country were outbreaks investigated to determine their sources. Few smallpox cases were reported in the south of the United Republic of Tanzania after 1969 but it later became apparent that the disease persisted in

border areas of Malawi and Southern Rhodesia, at least until the end of 1970. In Mozambique, however, no further cases were detected after 1969. Because security in many of the border areas was problematic, cases may well have occurred but remained undetected.

In Malawi, all cases after 1966 were reported from the south of the country. Southern Malawi presented an especially difficult problem. Large numbers of refugees from Mozambique lived in the region, most of whom crossed into the country through forest areas rather than at official border crossings. As illegal immigrants, they sought to avoid any contact with government authorities and often fled into the jungle when teams came to vaccinate. In order to contain outbreaks, villages were sometimes surrounded by a police cordon to prevent villagers from leaving the area until all had been vaccinated. In addition, some outbreaks were discovered during which variolation had been performed, supposedly in order to quell the spread. Cases which were detected were frequently reported as occurring among refugees from Mozambique or residents who had been in contact with them. Whether the cases represented new importations or continuing transmission among immigrants is unknown. Malawi reported only 61 cases in 1968 and 65 cases in 1969. In December 1969, the last case was reported by the health services. No cases were notified during 1970-1971.

By early 1972, it appeared that smallpox transmission might have ceased in the Malawi-Mozambique area. More than a year had elapsed since the last cases had been detected in Malawi and nearly 3 years since the last case had been reported in Mozambique. However, neither country was believed to have adequate surveillance programmes

I. D. LAONYI, 1967

**Plate 20.1.** Important foci of smallpox in southern Africa were situated along the border between Mozambique and Malawi, which was frequently crossed by Mozambicans fleeing the civil war. They were stopped and vaccinated if they used the official crossing points, but most went along forest trails and so escaped vaccination.

and thus doubts persisted as to whether smallpox was really absent. WHO staff could not participate in confirmatory studies in Mozambique but they could do so in Malawi. In April 1972, Dr Ziaul Islam, who had replaced Ladnyi as the WHO intercountry smallpox adviser, undertook a village-by-village field survey in areas of southern Malawi in which smallpox outbreaks had repeatedly occurred between 1966 and 1969. In 5 villages, he discovered 48 individuals with facial pockmarks who had developed smallpox in 1970 and 1971 (Table 20.6). The area was densely forested, populated with many refugees from Mozambique, including groups which, for religious reasons, refused vaccination. The first case that he could identify in the chain of transmission had

become ill in April 1970, and the last in February 1971. The earliest source of infection could not be specifically linked to previous outbreaks in Malawi although outbreaks had occurred in the same area in the past. During a vaccination scar survey in the affected area, Dr Islam found that 61% of children under 4 years of age, 84% of those aged 5–14 years, and 67% of persons aged 15 years and over had vaccination scars. Because of the proximity of the villages to Mozambique, the authorities there were notified. Mozambican teams subsequently undertook an extensive programme of vaccination and

search throughout the adjoining area in Mozambique but found no cases. During 1977, WHO and Malawian staff undertook a more extensive survey of the entire affected area in Malawi. They confirmed Dr Islam's earlier report but failed to detect further spread. They did, however, discover a pockmarked girl who was said to have become ill in September 1972, 19 months after the presumed last case in February 1971. Extensive investigation failed to reveal any other cases among family contacts and eventually it was concluded that the reported year of illness was erroneous. Malawi's last known case is

**Plate 20.2.** Variolator's kit obtained in 1966. Scabs and pustular material were carried in the bamboo stick; the awl was used for inoculation. Malawi was the only country in southern Africa where variolation was still being practised in the 1960s.

thus thought to have occurred in February 1971 in an outbreak which terminated spontaneously without being detected by health staff.

Southern Rhodesia's surveillance programme was little better than the corresponding programmes in Malawi and Mozambique, and the origin of its last outbreaks no less mysterious. Southern Rhodesia reported only 10 cases in 1968 (Victoria Province) and 33 in 1969 (19 in Manicaland Province and 14 in Victoria Province). The outbreaks were all within 100 kilometres of the border with Mozambique. Mass vaccination was reported to have been performed in the area of each outbreak but only occasionally did provincial medical officers investigate outbreaks to ascertain the sources of infection. Indeed, as a review of records in 1978 was to show, none of the cases occurring in 1969 was investigated to determine the source of infection; a report of 10 cases was found which had been received by the provincial medical officer but had not been transmitted to the national authorities. (These cases do not appear in the official records and are not included in Table 20.4 or Table 20.6.)

In 1969, Dr Keith Dumbell from the WHO Collaborating Centre for Poxvirus Research in London and Henderson from

Geneva began to correspond with Dr J. G. Cruickshank, a virologist at the University College in Salisbury, to encourage the taking of specimens from cases to confirm the diagnosis and to obtain virus strains for laboratory study. Subsequently, in March 1970, the Secretary of Health of Southern Rhodesia directed provincial medical officers to obtain such specimens, and Dr Cruickshank, employing electron microscopy and standard virus isolation techniques, began to process a flow of specimens (Swanepoel & Cruickshank, 1972). Throughout most of 1970, some of the specimens submitted showed herpes-varicella virus but none showed any poxviruses. No cases were reported to WHO from Southern Rhodesia during 1970 until 13 August, when a telex

**Table 20.7.** Malawi: number of reported cases of smallpox, by age group, 1960-1965<sup>a</sup>

≥16	266	9
Total	2 873	99

<sup>a</sup> Data by age group not available for 1422 other cases reported during this period.

from the government was received in Geneva reporting a case of smallpox. Because the notification had been made under provisions of the International Health Regulations, official inquiry to Southern Rhodesia was permitted: "Would appreciate receiving urgently further particulars on source of infection of recent smallpox case and confirmation of diagnosis. No known smallpox in recent months in eastern Africa within 325 miles of Chipinga District [the location of the case]." The reply, telexed a week later, indicated that the case had not been confirmed because the patient had left the hospital before being questioned and was thought to have returned to Mozambique. The official weekly reports from Southern Rhodesia subsequently reflected no cases; only much later was the case added to the official records.

No other cases were notified until November 1970, when the government reported, by telex, 2 further cases. The existence of these cases implied that there was a persistent focus of endemic smallpox, and undoubtedly many more cases had occurred to sustain the chain of transmission. Letters and telegrams were exchanged, but to little avail. Southern Rhodesia was eventually to record officially 6 cases in late 1970. Four were reported from Chipinga Town, 25 kilometres from the Mozambican border; 2 of them were considered to have been possible importations from Mozambique but the information available was too vague to confirm this. The remaining 2 cases were reported from another province near the border and confirmed by electron microscopic examination. Their onset occurred in December 1970. It was reported that the patients had been in Mozambique 2 weeks earlier, but again the investigation was perfunctory.

Over the succeeding 5 years, Dr Cruickshank examined 17 specimens taken from suspected cases of smallpox and others from patients with chickenpox and other rash-

producing illnesses. None proved to be smallpox. During 1978, in preparation for certification, extensive pockmark surveys were conducted to detect cases that might have been missed. Only 1 case was found, which had occurred in mid-1970, some 6 months before the last 2 cases were recorded. (This case does not appear in the official records and is not included in Table 20.4 or Table 20.6)

In summary, only 6 cases of smallpox were officially reported by Southern Rhodesian health staff during 1970-1971. Later, another 49 cases were discovered during special surveys in Malawi and 1 further case in Southern Rhodesia. Such investigations as were carried out suggest that persistent transmission may have continued throughout 1970 and possibly during the early months of 1971 in border areas of Mozambique as well as in Malawi and Southern Rhodesia. At all events, the number of cases was undoubtedly substantially greater than the official records indicate.

### Age Distribution of Cases

Information regarding the age distribution of cases is available for only a proportion of the cases from Malawi during 1960-1965 (Table 20.7) and for all of those in Mozambique in 1968 (Table 20.8).

Cases in Malawi occurred predominantly among children—a characteristic of endemic smallpox—during the period 1960-1965. In Mozambique during 1968, a larger proportion of cases was found among older persons, perhaps reflecting the fact that many cases occurred among more isolated groups living in sparsely settled areas. However, because reporting in both countries was incomplete, these data must be interpreted with caution.

## SOUTH AFRICA, BOTSWANA, LESOTHO, NAMIBIA AND SWAZILAND

### Background

South Africa, Botswana, Lesotho, Namibia and Swaziland are closely related geographically as well as by trade and commerce. South Africa is by far the largest of these countries, with a population of 22.8 million (in 1970).

Table 20.8. Mozambique: number of reported cases of smallpox, by age group, 1968

Age group (years)	Number of cases	%
<1	24	17
1-4	44	30
5-14	42	29
≥15	35	24
Total	145	100

The others had a combined population of only 3.2 million, many of whom were employed in South Africa, principally in mining, or travelled there regularly. An extensive, well-developed network of health services, roads and communication facilities extended throughout South Africa; the other countries had fewer resources of this kind.

The persistence of endemic smallpox in this part of southern Africa can be attributed primarily to the fact that, for more than 50 years, the predominant type of smallpox had been a form of variola minor which was even less severe and with a lower case-fatality rate than that in the Americas. Described first in South Africa in the late 1800s, it was known as "amaas" or "kaffir-pox" (see Chapter 5). Its mild character is illustrated by the fact that from 1922 to 1944, 9122 cases were notified in South Africa but only 17 deaths were recorded. Between 1945 and 1952, however, case-fatality rates tended to approach those associated with variola major in African countries to the north. But after 1952, variola minor again displaced variola major. From 1953 to 1971, only 13 deaths attributed to smallpox were reported, of which 11 occurred in 1964 (Table 20.9) during an outbreak of 54 cases in Port Elizabeth, Cape Province. This outbreak was attributed to an importation from Zambia. Evidence that the low case-fatality rate was not an artefact due to incomplete recording of deaths was provided

when variola minor spread from South Africa to Botswana in 1971. There, cases and deaths were much more carefully documented. Of 1122 patients, only 2 died.

Continuing vaccination campaigns employing liquid vaccine produced in South Africa had been in progress in each of the countries for many decades. The programmes were intended primarily to prevent large-scale outbreaks of variola major should it be reintroduced rather than to control the relatively innocuous variola minor, against which the vaccine also provided protection.

Until 1972, little information regarding the epidemiology of smallpox and the control programme in South Africa was available to WHO. That which was available was gleaned from a monthly infectious diseases bulletin published by the government and occasional reports of outbreaks sent to WHO by the Secretary of Health, in partial conformity with the International Health Regulations. Information regarding the geographical distribution of cases would have been helpful but the reports listed cases only by month and by racial group.

Data from South Africa, such as they were, were regularly included in published reviews which appeared in the *Weekly epidemiological record*. As country after country in Africa became free of smallpox, South Africa's dubious distinction as one of only a few endemic countries became politically intolerable to its authorities. Although the disease was not a public health problem, South Africa began to take an interest in smallpox in 1970 and commenced an intensive vaccination campaign in the endemic areas. Surveillance was incomplete, and it is therefore uncertain when transmission was actually interrupted. The last known endemic case occurred on 3 May 1971.

Only a few months later, neighbouring Botswana began to detect cases. Perfunctory control measures were taken but smallpox continued to spread. Not until May 1972, almost a year later, was an adequate programme begun. By then, the disease had spread widely across the country. Smallpox persisted in Botswana until November 1973.

### Lesotho, Namibia and Swaziland

Events in South Africa and Botswana are described in greater detail later in this chapter. Smallpox occurrence and programme

<sup>a</sup>.. = data not recorded.

activities in Lesotho, Namibia and Swaziland may be briefly summarized. Namibia (population in 1970, 1.04 million) was one of the most sparsely inhabited countries in southern Africa; its last known case of smallpox was reported in 1956. Vaccination programmes employing mobile teams which administered poliomyelitis and BCG vaccines as well as smallpox vaccine were well established and had been operative for many years. Because smallpox transmission had been interrupted throughout western South Africa and Angola by 1960 and in Botswana in 1964, the risk of importations was small. Even the 1971-1973 epidemic in Botswana posed little threat because the outbreaks were concentrated in the eastern part of that country, separated from population centres in Namibia by hundreds of miles of desert. Consequently, no special activities were undertaken in Namibia during the Intensified Programme.

Swaziland was first visited by Ladnyi in 1968 and Lesotho in 1970 to assess the status of their activities and to offer such assistance from WHO as might be required. Lesotho (population in 1970, 1.06 million), after many years of freedom from smallpox, experienced an outbreak of 84 cases in 1961. The outbreak extended through June 1962, 52 cases being reported that year. No deaths occurred. In 1961, 700 000 persons were vaccinated in a 3-month mass campaign and, thereafter, mobile teams supported by UNICEF vaccinated between 50 000 and 150 000 people each year, administering liquid smallpox vaccine simultaneously with BCG vaccine. In 1970, WHO began to provide freeze-dried smallpox vaccine for the programme. No further cases were found. Swaziland (population in 1970, 426 000) began experiencing smallpox outbreaks in 1963, its first since 1950. From 1963 to the end of 1966, 182, 517, 85 and 73 cases were notified for the respective years, but only 9 deaths were reported during the entire period. How many of these were genuine cases of smallpox is unknown. Of a series of 73 cases diagnosed as smallpox by auxiliary health workers, 55 were sent to hospital but none was confirmed clinically as smallpox by the physicians who saw them. In areas in which outbreaks occurred, between 44 000 and 90 000 vaccinations were performed each year from 1963 to 1966, using liquid vaccine produced in South Africa. In September 1967, a UNICEF-assisted mass vaccination campaign began, employing BCG and freeze-dried smallpox vaccine.

Between 1967 and 1972, when the mass campaign concluded, between 34 000 and 64 000 persons had been vaccinated each year. Thereafter, vaccination was performed by the health centres. A survey in 1970, 3 years after the programme had started, revealed that only 51% of persons under 15 years of age and 20% of those aged 15 and over had vaccination scars. The year in which smallpox transmission was interrupted in Swaziland is unknown. Twenty-five cases were reported to WHO in 1967, 20 in 1968, and 24 in 1969. Because of this, Swaziland was originally listed as an endemic country. However, government records reviewed during certification activities show no cases after 1966 and no one at that time could be found who knew anything about the cases that were said to have occurred between 1967 and 1969. Whether these cases represented clerical error or were indeed cases of smallpox could not be ascertained. As in most countries of southern Africa, smallpox transmission had ceased spontaneously during the course of an indifferently executed vaccination campaign. When surveillance programmes eventually began, no cases could be found.

### South Africa

Richly endowed with natural resources and with a large and expanding industrial base, South Africa had many of the attributes of developed countries in temperate climates. Almost half of South Africa's population of 22.8 million (in 1970) lived in urban areas. Preventive health services were administered by regional medical directors, 2 of whom were assigned to the 2 larger provinces (Cape and Transvaal) and 1 each to the 2 smaller (Orange Free State and Natal). They, in turn, oversaw the work of medical officers of health in each local authority. The pattern of vaccination activities differed somewhat from province to province but, in general, all provided vaccine through health centres and clinics, and supplemented this in rural areas by mobile teams which performed vaccinations at collecting points. Poliomyelitis, smallpox and BCG vaccines were administered to young children and smallpox vaccine to older children and adults. The smallpox vaccine, until 1970 a liquid vaccine, was produced at the State Vaccine Institute in Cape Town. Vaccination was also given to all children at school entry, and to the 100 000 or

so men who came each year to work in the mines. From 1968 to 1975, between 600 000 and 900 000 persons received smallpox vaccine each year through government facilities. The number of vaccinations was small in proportion to the population, but the total did not include those, said to be many, that were provided by private physicians.

Reporting from the more than 10 000 health units which regularly saw patients was thought to be reasonably good, but because smallpox in South Africa was so mild, the government authorities believed that many persons with smallpox did not seek medical attention and so did not come to the attention of the health services. Teachers and heads of families were also supposed to report cases when they occurred but their level of compliance was uncertain, especially in areas in which religious sects objected to vaccination of any type.

Information about smallpox was very incomplete for other reasons. Responsibility for health problems, as well as the investigation and control of outbreaks of smallpox and other diseases, was regarded as a provincial responsibility, and in the provinces, as mentioned above, this function was primarily discharged by local medical officers of health. Diligence in the investigation of cases and the conscientiousness with which notifications were forwarded varied from area to area. Since the mild *variola minor* caused the provincial health authorities little concern, not much time was devoted to the investigation or control of outbreaks. The problem was compounded by a national morbidity reporting system considered to be so unsatisfactory that in 1970 a complete

Fig. 20.6. South Africa: number of reported cases of smallpox, by year, 1961-1973.

restructuring of the system was begun. Pending completion of this effort, national morbidity reports ceased to be published in March 1970. Until 1978, further data regarding cases and their geographical location, as notified nationally, were not made available to WHO. When reviewed by WHO in 1978, reports revealed that the Transvaal accounted for most of the cases after 1960 and for all but 41 of the 502 cases reported after 1966 (Table 20.10).

South Africa reported only 43 cases to WHO during 1967, and 81 cases in 1968. Because so few cases were being reported in a country in which health services were so extensive, WHO had originally assumed that these cases must have occurred following importations and had provisionally classified South Africa as a non-endemic country.

In 1969, however, the number of reported cases increased (Fig. 20.6; Table 20.10). Because communication with South Africa through the usual official channels was not possible, Henderson addressed a personal letter to the Secretary for Health on 27 August, noting that as of that date: "South Africa now accounts for about 10% of all cases recorded in Africa this year" and asking for a fuller statement of the epidemiological situation as well as a description of the problems being encountered in controlling spread. By the end of that year, 246 cases had been reported to WHO.

A reply was not received until February 1970. In his letter addressed to Henderson at WHO, the Director of Medical Services showed a dismayed lack of understanding of

<sup>a</sup> Case imported from Botswana.

the epidemiology of smallpox. He asserted that the cases were sporadic and explained that, with variola minor, "very mild undetected cases and subclinical cases, harbouring the virus in their tonsils, the lymph follicles of the tongue and pharynx are liable to spread the disease to every person not vaccinated against smallpox. Due to this mode of spread, a population with a successful vaccination rate of more than 80% is not protected." He indicated that mass vaccination would continue in order to limit the spread of disease. In reply, Henderson pointed out that in Brazil, in which variola minor was also endemic, "smallpox is transmitted only by cases with definite lesions of smallpox and during the period... of rash... and that 80-90% of cases can be traced to personal contact in a house." The favourable experience of other countries in investigating and containing each outbreak was noted and procedures for outbreak containment were described. What effect this correspondence had is unknown.

As it was later learned, the most important stimulus which precipitated a more vigorous programme in South Africa was the WHO Director-General's report on smallpox eradication, prepared as a document (EB45/16; dated 1 December 1969 but never published in WHO's Official Records) for the forty-fifth session of the Executive Board in January 1970 and obtained by South Africa. The report stated:

"Of the endemic countries in Africa, South Africa and Ethiopia are the only ones which have not yet initiated eradication programmes. The number of cases recorded this year by South Africa more than doubled [246 cases in 1969 compared with 81 cases in 1968] ... However, little additional information is available ... The continuing reservoir of smallpox in South Africa and Ethiopia is of increasing concern to neighbouring countries, most of which have become, or are rapidly becoming, smallpox free ... With only three known exceptions, freeze-dried vaccine of satisfactory potency, stability and purity is now used in all endemic countries. However, in South Africa, liquid vaccine continues to be employed..."

South African health officials were angered by the report, considering it to be unfair for three reasons. The first was that the report and the tables of data referred to smallpox only generically, drawing no distinction between the severe variola major of Asia or many other countries of Africa and the mild form of variola minor present in South Africa. This,

however, had been a policy followed by WHO since the inception of the programme because the mandate of the World Health Assembly was the eradication of smallpox of whatever variety. The second was the issue of whether or not South Africa could be said to have an eradication programme. As the health authorities viewed it, an effective vaccination campaign was being conducted throughout the country and local authorities were expected to control outbreaks when these occurred. In WHO's view, however, an eradication programme had as its objective the complete interruption of smallpox transmission, an unrealistic aim as seen by the South African Director of Medical Services. The third reason was the emphasis on the use of freeze-dried vaccine—clearly of importance in tropical countries in which ambient temperatures were high and refrigerated storage was scarce. In South Africa, however, ambient temperatures were not so high and refrigerated storage for vaccine was not considered a problem. WHO's emphasis on the need for freeze-dried vaccine in endemic areas was based on the recognition that even when refrigerated storage was adequate, health and medical personnel, even in industrialized countries, often failed to preserve vaccines properly.

Although highly sceptical that other African countries were making as much progress as was claimed, the South African health authorities decided early in 1970 to take additional measures to control smallpox and, by so doing, avoid the expected criticism of other independent African countries. A special programme was launched to produce large quantities of freeze-dried vaccine; by May, all mobile vaccination teams were using this. The vaccine was said to meet WHO standards although it was not examined by a WHO reference laboratory. By the end of 1970, liquid vaccine was being provided only to private practitioners.

In June 1970, an intensified systematic vaccination campaign was begun in the northern Transvaal, from which most smallpox cases were reported. It was termed a house-to-house campaign although, for convenience and efficiency, vaccinators usually assembled persons from a group of neighbouring houses. By the end of the year, more than 350 000 persons had been vaccinated. This represented only a small proportion of the 6.3 million people then resident in the province, although coverage in

the infected but sparsely populated northern areas was said to be high.

By the end of June 1970, 117 cases had been reported to WHO, but thereafter none was notified until December (4 cases) and again in January 1971 (7 cases). As was learned only much later by WHO, all were in the Transvaal, not far from the border with Botswana (Fig. 20.7). Reports from South Africa then ceased. Repeated inquiries were made by WHO officials and others in South Africa after January 1971, under the provisions of the International Health Regulations, asking for confirmation that no further cases had occurred, but there was no response. It was unclear whether there were indeed no cases or whether the government had decided not to report any more cases of smallpox to WHO.

In June 1971, Botswana reported a case of smallpox in Gaborone, the capital, but 2 weeks later asserted that the case had actually been chickenpox. In August, additional cases were reported and these were confirmed as smallpox by laboratory examination. The information was promptly relayed to South Africa and Southern Rhodesia, and teams from both countries immediately went to border areas to conduct intensive vaccination campaigns. The Botswana outbreak continued but only 1 case is known to have been reimported into South Africa—in a labourer who became ill on 14 February 1972.

The question of concern in the autumn of 1971 was how and where smallpox transmission was being sustained in the South Africa-Botswana area. As has been noted, South Africa had reported 11 cases during the 2-month period, December 1970 to January 1971, after 5 months during which no cases had been notified. Following this, 7 months had elapsed before cases were confirmed in Botswana. It was certain that many additional cases had occurred during these two intervals in order to sustain the chain of transmission. Discovery of the infected area was important. Botswana, whose surveillance system was poor, was a candidate area but, because of the letter from South Africa's Secretary for Health, the programme in the latter country had to be regarded with suspicion. WHO Headquarters staff believed it imperative that a visit should be made to South Africa, as well as to Angola and Mozambique, to assess the situation. This was proposed on the grounds that such contact with South Africa was permissible under the terms of a resolution adopted by the WHO Executive Board

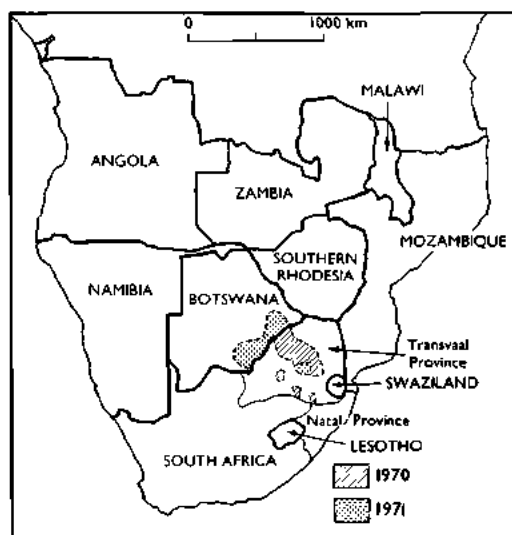

Fig. 20.7. Southern Africa: areas known to have had endemic smallpox, 1970-1971.

(EB45.R20), endorsed by the Twenty-third World Health Assembly in resolution WHA23.46, which had requested the Director-General "to continue to take all necessary steps to assure the maximum co-ordination of national and international efforts". This, it was felt, implied licence to visit South Africa. The proposal was discussed at length and eventually agreement was reached between WHO and the South African government that Henderson should visit South Africa, which he did in June 1972.

In the Transvaal, he found a well-organized vaccination campaign in progress, with attention being given to the detection and laboratory confirmation of suspected cases. During 1972, only a single importation from Botswana had been detected, but health officials were alert because they believed there would be more—if not from Botswana, perhaps from Angola or Mozambique, which they believed continued to harbour endemic smallpox even though neither reported cases.

However, when Henderson endeavoured to obtain epidemiological data regarding the cases reported in 1971, it became apparent that there had been many more cases of smallpox than had been reported to the national authorities. Official records at that time showed only the 7 cases which had occurred in January 1971, in a hospital some 300 kilometres from the border with Botswana. On the other hand, a review of records

at the National Institute for Virology, Sandringham—the diagnostic reference centre—showed 10 poxvirus isolations during 1971, the last from a patient who became ill on 3 May 1971.

The laboratory itself, well equipped and well staffed, was in part inadvertently responsible for problems in smallpox control. It employed an unorthodox approach to the examination of specimens. Standard virological technique called for the isolation of virus on the membrane of fertile hens' eggs. By visual examination of the pocks that grew, variola virus could readily be distinguished from vaccinia virus. At the Institute, the specimens were grown in tissue culture in which, if virus growth occurred, it was impossible to discriminate with certainty between variola virus and vaccinia virus. Accordingly, the laboratory reported only whether or not a virus of the "vaccinia-variola virus group" had been isolated. The laboratory director's view was that whoever sent the specimen should be able to make a clinical distinction between smallpox and disseminated vaccinia, and thus he saw no need to differentiate the viruses by laboratory study. Recipients of the reports, however, sometimes misinterpreted them and reclassified cases of smallpox as vaccinia.

Cases and outbreaks were notified to the regional medical directors by local health officials, who controlled any outbreaks that were found with varying levels of diligence. At neither the national nor the provincial level was there a health official responsible for ensuring that the outbreaks were properly investigated and contained. In no instance had an effort been made to trace the spread of smallpox or to define endemic areas. Reports of variola virus isolations by the reference laboratory were made known only to the persons submitting the specimens; provincial officials were not provided with copies of the reports.

Following Henderson's visit in June 1972, health officials endeavoured to reconstruct the epidemiological pattern of spread of smallpox during 1971. This was important, for if it could be shown that the cases had been closely related and the outbreaks contained, there would be greater assurance that South Africa by 1972 was indeed free of smallpox. Conversely, if the cases had been scattered and unrelated to each other, widespread and perhaps continuing endemicity was implied.

The investigations eventually revealed that smallpox had indeed persisted in South Africa until at least May 1971, all the cases occurring after February having acquired the infection at a hospital about 100 kilometres north of Pretoria, in the Transvaal. As far as the outbreak could be reconstructed, 3 unvaccinated children from a village 30 kilometres distant were hospitalized with typical smallpox in January and February 1971 and the diagnosis was confirmed by virus isolation. The mother reported that her other 4 children, as well as a number of children in the vicinity, had been ill with a similar disease. Three additional children from the same village were admitted with smallpox during January and February, although no specimens were collected. On 26 March, a child hospitalized with tuberculous meningitis and receiving steroid therapy developed a rash at first thought to be drug-induced. Specimens were taken and the National Institute for Virology reported the isolation of a virus of the vaccinia-variola group. The report was misinterpreted and it was concluded that the child had experienced disseminated vaccinia. The patient died on 3 April. Three additional cases occurred in previously hospitalized children on 12, 14 and 19 April respectively, all of which were confirmed by virus isolation. The Regional Medical Director, who was asked to investigate, reported as follows:

"The suspected outbreak has occurred in the TB ward. One death [not officially notified] is attributed to the disease which had been diagnosed also in 3 other children who were examined. In addition, 3 cases of healing chickenpox were examined. According to my information, the latter disease has been "endemic" amongst children in this ward for many months. That is to say chickenpox has been diagnosed also amongst other children who have no visible lesions now and also in children who have been discharged already ... Vaccination of patients and personnel ... carried out 7 April did not give a satisfactory percentage of takes ... The ward was placed in quarantine only this week. Therefore, a list was compiled of all inmates and also of all patients discharged ... The homes of all will be visited by departmental field staff."

A large hospital-based outbreak of smallpox and possibly of chickenpox had obviously been in progress for at least 2 months. Extensive vaccination campaigns were conducted subsequently in the many

areas from which the hospital patients had come. Three additional cases were found, all of whom had been infected at the hospital: a child who had been hospitalized became ill on 3 May, and 2 labourers who had been seen in the outpatient department 2 weeks earlier became ill in March on a farm 100 kilometres distant. In all, 10 cases and 1 death appear on the official records for 1971 but, as is apparent from this account, there were at least 20 cases and possibly many more. Fortunately, the outbreak occurred at the end of the summer, the low point in seasonal transmission, so that despite greatly delayed containment measures, smallpox spread slowly and transmission was soon interrupted.

In South Africa, as in other countries of southern Africa, extensive vaccination rather than an organized surveillance-containment programme served to interrupt transmission. During the continuing vaccination campaign, no further cases were detected and none was reported by the 11 000 reporting units. Among 77 specimens submitted to the laboratory over the period 1972-1977, only 1 further isolation of the "vaccinia-variola group of viruses" was made, the specimen concerned being from the case (see above) that was imported from Botswana in 1972.

### Botswana

Botswana, which became independent in 1966, is large but sparsely populated, the great Kalahari desert extending over the south-west portion of the country and occupying more than half the land area. Over 80% of its population of 623 000 (1970) lived along a strip of land in the south-east, not more than 200 kilometres wide, adjacent to the Transvaal Province of South Africa. Travel between Botswana and South Africa was frequent; population movement within the country was extensive and followed an unusual pattern. A large proportion of the population maintained 3 dwellings: one in a village, a second at a cattle post and a third in a farming area. Family members spent time each year in the different locations, which were often widely separated. Moreover, an estimated one-third of the adult males left rural areas each year seeking employment in the country's urban areas or in South Africa. Government health facilities were comparatively numerous; in 1966 there were 7 hospitals, 73 clinics and 65 health posts.

Several missionary groups also provided medical care.

In this small and scattered but highly mobile population, smallpox was characterized by periodic outbreaks followed by long intervals with few or no cases. An outbreak of 175 reported cases and 34 deaths in 1964 was controlled by a mass vaccination campaign and during the following 6 years only 1 case was notified (Table 20.11).

Because Botswana was believed to be smallpox-free when the Intensified Smallpox Eradication Programme began and because adjacent countries were reporting few or no cases, the development of a special programme was not considered by WHO to be of high priority—if it was required at all. As time passed, the apparent need for a programme diminished. Neighbouring Namibia and Angola reported no cases and Zambia became smallpox-free in 1968. The only other

a. . = data not recorded.

adjacent countries notifying cases, South Africa and Southern Rhodesia, reported so few in 1967-1968 that WHO suspected that they were the result of importations rather than of endemic transmission. By the end of 1969, however, the number of reported cases in South Africa had increased so greatly that it seemed certain that endemic smallpox was present there. Although the government informed WHO that some of the cases were in Transvaal Province, their exact whereabouts were not revealed. Only in 1972 did it become known that virtually all the reported cases had occurred in the Transvaal, many near the border with Botswana.

Ladnyi paid his first visit to Botswana in January 1971 to discuss the status of its vaccination campaign and the assistance that WHO might be able to offer. After Botswana's mass vaccination campaign of 1964, some vaccination activities had continued (Table 20.12). Liquid vaccine from South Africa had been employed up to the end of 1969, and thereafter freeze-dried smallpox vaccine, also purchased from South Africa, was used. Vaccinations were given by mobile teams in 3 of the 6 health districts and offered by hospitals and clinics throughout the country. However, the health facilities for the most part vaccinated persons leaving for South Africa and Zambia, both of which countries required certificates of vaccination. The number vaccinated each year was equivalent to no more than 5-10% of the population. The proportion of successful vaccinations is unknown but was probably not high even when freeze-dried vaccine began to be used. The freeze-dried vaccine was provided in 100-dose containers and was normally used for 1-2 weeks after reconstitution, although its potency would have fallen to nil within 2-3 days.

Ladnyi found that 80% of the pre-school children had no vaccination scar, and in a school near the capital whose pupils had recently been vaccinated by a mobile team, only 136 of 334 children (41%) had a vaccination scar. Better handling of the vaccine was obviously needed and he provided appropriate advice.

Ladnyi was concerned that smallpox might be imported, and his principal recommendation was that every suspected case of smallpox should be treated as an emergency and all necessary containment measures carried out with a minimum of delay. He recommended that a specimen should be taken from each

suspected case and sent to WHO Headquarters for examination; meanwhile the suspected case should be dealt with as though it were smallpox. In a country in which vaccinal immunity was so low, there was a special need for prompt action. The government requested vehicles and vaccine in support of the programme, a request which was forwarded to the WHO Regional Office for Africa.

On 1 June 1971, only 5 months after Ladnyi's visit, a cable was received in Geneva from Botswana reporting a case of smallpox. At that time, no cases had been reported from anywhere in southern Africa since January, although it was learned later that cases in South Africa continued to occur through May. Cables sent on 4 and 8 June from Botswana indicated that the case was in a patient already hospitalized in Gaborone, and that it had been confirmed virologically at South Africa's National Institute for Virology.

Urgent action was indicated. However, permission for WHO Headquarters staff to visit a country required the prior agreement both of the WHO regional office concerned and of the country itself. Henderson immediately telephoned the regional office in Brazzaville to point out the urgency of rapid containment and of a thorough investigation and to propose that an experienced epidemiologist from Headquarters should visit Botswana immediately. The regional office contacted Botswana and, on 16 June, reported that a cable had been received from the government indicating that the situation was misunderstood, that the case had turned out to be chickenpox, and that no visit was required. A return telex from Geneva to Brazzaville again urged an early visit by a WHO adviser in view of the fact that the case was said to have been confirmed by laboratory investigation. The regional office replied that such a visit was not considered advisable.

On 27 August, additional cases of smallpox were reported from Botswana, and specimens were sent by the government direct to Geneva. By 6 September, the WHO Regional Reference Centre for Smallpox in Atlanta, USA, had confirmed the isolation of smallpox virus. This caused a flurry of telex messages and letters between Geneva and Brazzaville. Headquarters staff repeatedly urged an emergency visit by Arita, pointing out that the Botswana focus presented a continuing threat to Botswana as well as neighbouring coun-

tries and noting that this was clearly as much an international as a national problem. The regional office requested more information from Botswana and asked whether WHO assistance was required.

On 7 September 1971, a letter was received in Geneva addressed to the Chief of the Smallpox Eradication unit from the Director of Medical Services of Botswana. Contrary to the cabled information received by the regional office, he reported that in May a 3-year-old child, hospitalized for tuberculosis, had developed smallpox and that a second case had been detected in a government employee in Gaborone on 16 August. Specimens from both had been confirmed as "vaccinia-variola type virus" by the South African National Institute for Virology. The second case had been vaccinated during a June vaccination campaign in Gaborone but showed no scar. The Director of Medical Services noted that "... no source of infection has been identified. There must, however, be a focus of infection somewhere".

On 20 September, Botswana requested a supply of freeze-dried vaccine—which was immediately sent from Geneva—and an operations officer to organize a vaccination campaign. However, as a new intercountry smallpox adviser, Dr Islam, had just replaced Ladnyi, whose current term of service in WHO had expired, he was sent instead. Unfortunately, despite his experience in the control of communicable diseases, he had not yet had direct experience with smallpox eradication and had not yet been briefed regarding techniques for surveillance and containment.

He arrived for a 15-day visit on 8 October by which time 3 additional smallpox cases had been detected and a fourth suspected case had been admitted to hospital. He was unable to trace the sources of these cases. The cases he did identify were in people who presented themselves at the hospital, and he indicated that "there is strong evidence that a smallpox focus exists... in the southern part of Central District... the investigations do not support the notion of recent importation". A mass vaccination campaign was said to have been conducted but, in fact, only 38 600 vaccinations had been recorded between January and August 1971. In the area of the smallpox focus, he found that 80% of 1767 primary-school children and 60% of 541 pre-school children had vaccination scars. In adjacent areas, however, only 20% of those aged 0-6

years had ever been vaccinated. He recommended a mass vaccination campaign in the primarily infected area, offered advice to the government regarding vaccine handling and vaccination technique and stressed the importance of surveillance. At this time, these were the only known cases of smallpox in the entire WHO African Region, the other countries in the African continent in which the disease was still endemic, Ethiopia and the Sudan, both then being in WHO's Eastern Mediterranean Region.

Cases continued to be reported from Botswana and all specimens sent for examination to the WHO collaborating centres were confirmed as smallpox, but no information was provided by the government as to what was being done to control the spread of the disease. Faced by frequent and increasingly urgent requests from WHO Headquarters to respond to Botswana's request for an operations officer, the regional office could only reply that no action could be taken unless it received an official application from the government.

In November 1971, an unexpected opportunity arose that permitted direct communication with Botswana. Mr John Phillips, the Resident Representative of the United Nations Development Programme in Botswana, stopped in Geneva on the way back to his duty station. After a full discussion of the problem with WHO staff, it was agreed that he would discuss it with government officials and ask them to submit a formal request to the regional office for the immediate assignment of an operations officer. The request was made forthwith, and Dr Pierre Ziegler, in charge of smallpox eradication in Zaire, was asked to make available his most experienced operations officer, Mr Garry Presthus (see Chapter 18, Plate 18.5). His transfer was not, however, arranged until the end of February 1972, nearly 9 months after Botswana had notified its first case.

On arrival, Mr Presthus, with his counterpart, Mr J. B. Sibiya, Senior Health Inspector for Botswana, rapidly set in motion a mass vaccination campaign and a programme which, unique among the programmes of southern Africa, emphasized the prompt detection of cases and their containment through vaccination. More than 18 months would elapse, however, before transmission could be interrupted.

Within a month of his arrival, Mr Presthus had met the director of the Botswana Red

G.T. PRESTHUS, c. 1973

G.T. PRESTHUS

**Plate 20.3.** **A:** Joseph B. Sibiya (*far left*), Senior Health Inspector, with one of Botswana's 4 surveillance teams. **B:** Many cases of smallpox were discovered in remote cattle posts in the Kalahari desert by the teams.

Cross, Ruth Seretse Khama, to explain the importance of smallpox eradication in Botswana and its significance for the global programme. In mid-April 1972, her husband, Sir Seretse Khama, the President of Botswana, had signed a special bill allocating US\$25 000 from the government budget. Although not a large sum in comparison with

funds provided in some other eradication programmes, this represented a substantial commitment for Botswana.

Using such vehicles as could be borrowed from other programmes, Mr Presthus and Mr Sibiya formed 4 teams to contain outbreaks in known foci and to encourage the network of health facilities to begin vaccinating both

people attending clinics and the inhabitants of nearby villages (Presthus, 1974). By early May 1972, forms had been prepared to be used for weekly reports from each health unit. Volunteers of all types offered assistance.

Field investigations conducted during March documented 36 cases which had occurred during 1971, the first in March near the South African border. Mr Presthus believed that there had been many more cases, but with new cases being detected daily there was no time to document further the previous year's experience.

In 1972, the number of reported cases increased to 63 in April and to 66 in May (Table 20.13). In that month, one of the cases was reported from Ngamiland, in the north-western part of the country, an area of great concern because of the frequent movement of rebel forces between it and areas in south-eastern Angola which were only partially accessible to the government of Angola. A surveillance team was hurriedly sent to the area, but fortunately there was an able District Medical Officer, in Ngamiland, Dr Nicholas Ward, who had already organized the health staff for extensive vaccination and search activities. Only 5 other cases were eventually detected in Ngamiland. A year later Dr Ward was recruited by WHO, which he served with distinction in smallpox eradication work in Bangladesh and India.

The increase in the number of cases in April and May 1972 was of profound concern. Although little was known of past seasonal trends of smallpox in Botswana itself, it was assumed that more rapid transmission would occur during the cooler months of the year, from June to the end of October. Accordingly, at the end of May, the WHO intercountry smallpox adviser was directed to assist Mr Presthus and Mr Sibiya in surveillance-containment operations.

Hospital and clinic staff meanwhile had responded enthusiastically to the request that they should vaccinate people in nearby villages, and by the end of July more than

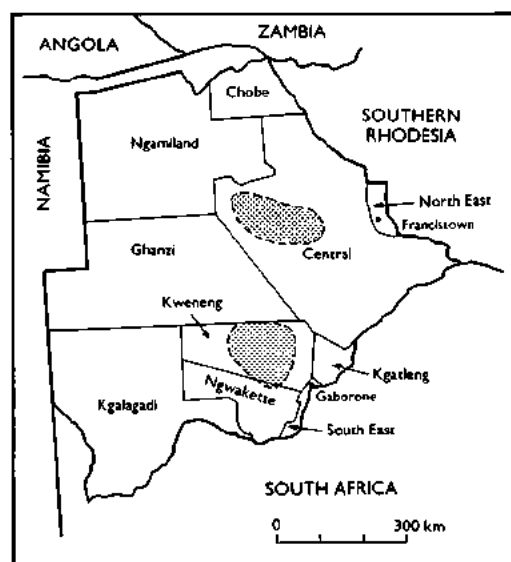

Fig. 20.8. Botswana: areas affected by smallpox, by district, at the end of July 1972.

200 000 had been vaccinated—5 times as many as were customarily vaccinated in an entire year. Meanwhile, the 3 surveillance teams sought to detect and contain outbreaks. The investigation of 48 hospitalized cases revealed 321 others. Because many were being traced to Kweneng District (Fig. 20.8), a systematic search was conducted throughout this area, revealing another 355 cases. Virtually all the cases were detected at cattle posts in rural areas, far distant from the clinics and health posts. Meantime, a second but less seriously affected area was found in Central District.

The number of cases detected increased to 121 in June and to 565 in July. Most were in Kweneng and Central Districts (Table 20.14). Analysis of 39 outbreaks comprising 353 cases revealed an average of 9 cases in each outbreak with a range of 3–30 cases; one-fourth of the outbreaks had persisted for 4 or more genera-

tions of disease. The interruption of transmission was difficult, however, because the mildness of the disease permitted infected persons to travel between their different residences, which they did frequently.

Lack of vehicles hampered the work of the smallpox eradication teams. Four Land Rovers had been ordered in February but, despite efforts to speed their delivery, they did not arrive until November 1972. Nevertheless, the teams organized by Mr Sibiya and Mr Presthus worked tirelessly, and by the end of the year 402 000 persons had been vaccinated. From July onwards, 83% of the 19 designated reporting units sent in weekly reports, although some of these were not received until 1 or 2 months after dispatch because of the poor postal service. Accordingly, health staff throughout the country were instructed to use the telephone or telegraph if a case was found. However, an analysis of reports at the end of November showed that only 5% of cases were seen by the health care units, the remainder being detected by outbreak investigation and active search.

Although it was the season of high transmission, the numbers of cases decreased sharply after July. Meanwhile, in response to warnings about the problem in Botswana, South Africa and Southern Rhodesia undertook extensive vaccination campaigns throughout their border regions, and in Angola, military forces were employed in vaccinating the inhabitants of large areas in the south-east. They detected no cases.

Although resources available to the programme were limited and the population was widely scattered, relatively high levels of vaccinal immunity were achieved in less than a year (Table 20.15).

The search for cases continued after November 1972 but none was found until March 1973. On 7 March, a 22-year-old man was admitted to the hospital in Gaborone with suspected chickenpox, which proved to be smallpox. A house-by-house search began in the vicinity of the patient's home; it was extended to Gaborone and, finally, to a cattle post, 40 kilometres away, in which the patient had spent a night. No other cases could be found until, after 3 weeks of search, a schoolchild identified a person who had recovered from smallpox and was being hidden from the teams. The patient was a member of a Christian sect, known as the Mazezuru, which opposed medical treatment and resisted vaccination.

The search was then focused on Mazezuru families, and 19 cases were eventually identified, the first having been infected in late September 1972 in Kweneng District in an area in which the last cases had been detected that year. Two slowly spreading chains of infection had developed: one chain consisted of 9 cases in Gaborone, of whom all but the hospitalized patient were Mazezuru; and one chain of 10 cases in a town 400 kilometres to the north, in which 4 Mazezuru had been infected. The last of the cases occurred on 13 April 1973.

G. I. PRESKHUS

**Plate 20.4.** The child in this Mazezuru family developed smallpox on 7 November 1973; another patient with the same source of infection, who became ill on 15 November, was the last known case in Botswana.

Active search continued, with special attention to the Mazezuru. This sect was estimated to comprise only 3500–5000 persons, who lived in 9 closed or semi-closed communities in towns near the railway. They were traders who travelled frequently to visit relatives and friends in South Africa and Southern Rhodesia as well as in other areas of Botswana. Fortunately, they were distinctive in that the women wore all-white clothing and the men were frequently bearded. So strongly did they object to vaccination that on one occasion in April a community of 100 persons left by train when they learned that a team was coming to vaccinate them. Extensive discussions with Mazezuru church leaders led to a verbal agreement that they would persuade their people to accept vaccination. Later, it was learned that the leaders had privately advised the members of their sect to refuse to cooperate.

From April to September, no cases were detected, but in September another case appeared at a hospital; the patient was a non-

Mazezuru girl who lived in the Mazezuru quarter of a migrant settlement near a mining complex. Five weeks of intensive search turned up 5 more cases, but from discussions with people living in the area, it was suspected that at least 6–10 additional cases had occurred. The first patient had become ill in June and the last on 14 September. Again, nearly 2 months elapsed, when, on 21 November, yet another case was found in the mining camp, and this in turn led to 2 more cases at the camp and 3 cases in Gaborone, the last of whom had become ill on 15 November.

More stringent measures were required to interrupt the tenuous but tenacious chain of transmission among the Mazezuru. Most Mazezuru were comparatively recent immigrants to Botswana, having come mainly from Southern Rhodesia. To enter South Africa or Southern Rhodesia they were obliged to be vaccinated and they accepted this as a necessity. Mandatory vaccination in Botswana was proposed to the President of the country. He concurred and informed Mazezuru leaders that either their co-religionists must accept vaccination or they would be deported. They agreed to be vaccinated.

From 1974 onwards, both smallpox and BCG vaccinations were administered by the health facilities in substantial numbers, scar surveys in 1974 revealing an overall level of vaccinal immunity of 95%. The 4 surveillance teams continued to encourage and supervise this activity and to search for cases. Many suspected cases were investigated and specimens examined but none proved to be smallpox.

Information regarding the age and vaccination status of cases is shown in Table 20.16. Nearly half the cases occurred in individuals aged between 5 and 14 years. The occurrence of 34% of cases among adults is

**Table 20.16.** Botswana: number of reported cases of and deaths from smallpox, by age group and vaccination status, 1971–1972<sup>a</sup>

Total	1 082	32	2

<sup>a</sup> Further details not available for 13 other cases reported during this period.

high compared to the situation in most countries, but it is not unexpected considering the low level of vaccinal immunity in Botswana. Cases in infants (0-12 months) were thought to have been underenumerated because of the tendency of parents to hide young children with smallpox. Thirty-two of the cases (3%) were reported to have had a vaccination scar, but some of these were individuals vaccinated late in the incubation period. Only 2 deaths are known to have occurred (a reflection of the mildness of the disease); one of them was the child with tuberculosis, already mentioned, who was receiving steroid therapy and the other was a 2-week-old infant.

### ANGOLA

Angola (population in 1970, 5.6 million) reported no case of smallpox after 1966. It had an extensive network of hospitals, health centres and rural dispensaries which offered smallpox vaccination. In addition, 300 "rural agents" travelled through assigned areas of the countryside giving vaccinations. Separate mobile units, numbering 26 in all, dealt with leprosy, trypanosomiasis and tuberculosis; they also administered smallpox vaccine. Freeze-dried vaccine obtained from Portugal, France or Switzerland had been used since the mid-1960s. Because freeze-dried vaccine was in use and the number vaccinated annually amounted to 30-60% of the population, vaccinal immunity was probably high. Until 1959, when transmission appears to have been interrupted, variola minor was the prevalent strain: among 1712 cases reported between 1950 and 1959, there were only 23 deaths. Outbreaks due to smallpox imported from Zaire occurred in 1962 (23 cases), 1963 (50 cases), 1964 (1 case) and 1966 (3 cases). Each was investigated by epidemiologists from Luanda, the capital, and confirmed by virus isolation at a laboratory there. The extensive national programme of vaccination continued until the end of 1974, a special campaign being conducted in 1971-1972 in areas adjacent to Botswana; no imported cases were discovered after 1966. Vaccination and surveillance activities were sharply curtailed during 1974-1975, when civil war erupted, but by then more than 2 years had elapsed since the major outbreaks in Botswana and more than 3 years since the last cases had occurred in Zaire.

### CONCLUSION

As had been expected in 1967, smallpox in southern Africa was not a major problem, but transmission continued far longer than had been anticipated. Constraints on official communication between WHO and the health authorities in several of the countries or areas unquestionably inhibited progress. In most instances, national health officials were capable of investigating and containing outbreaks, but they needed instruction and assistance to carry out the task in a proper manner. Because the incidence of smallpox was low, effective surveillance and containment might have interrupted transmission much earlier and the final epidemic in Botswana would not have occurred.

Considering the extensive number of health units and special vaccination campaigns in operation throughout southern Africa, it is perhaps surprising that smallpox was not eliminated from this area long before 1967. However, in many of the countries few of the health units offered vaccination, even to people attending their clinics. Moreover, except in Angola and Mozambique, liquid vaccine was the only type of vaccine used, and when supervision was poor, as in Botswana, Malawi and Zambia, the vaccine was not properly refrigerated and there were comparatively few successful takes. When freeze-dried vaccine became widely available, the numbers of cases of smallpox diminished rapidly and transmission was soon interrupted, even though, with the exception of Angola and Botswana, few outbreaks were investigated or contained.

The concluding episode in southern Africa—namely, the reinfection of and extensive spread of smallpox in Botswana—was regrettable and, in retrospect, avoidable. Re-establishment of endemic smallpox might have been averted if a programme in Botswana had been initiated a year or more earlier. That Botswana was at significant risk, however, had not been appreciated. The principal endemic focus of smallpox in South Africa was in the Transvaal, near the border with Botswana, but this was not made known to WHO until after smallpox had become endemic in Botswana. For their part, the South African authorities had been little concerned with the mild variola minor that was present and rarely investigated or contained the outbreaks that did occur. However, even as late as June 1971, when the

first case was reported in Botswana, prompt action might have aborted the ensuing epidemic. Unhappily, there was a delay of fully 9 months before an effective programme began. By then, an intensive and more costly effort was required to stop transmission. Botswana's programme, once begun, was imaginatively and competently executed—the best of any in southern Africa.

The exceptionally mild form of variola minor found in Botswana and South Africa did not constitute a problem of public health

significance; had this form of smallpox prevailed throughout the world, a global eradication programme would not have been warranted. It was clear, however, that unless smallpox as a disease, whatever its degree of severity, were eradicated, long-standing programmes of vaccination and the issuing of vaccination certificates for travellers would continue to be required. The eradication of variola minor in Botswana and South Africa was as important to the global programme as was the eradication of variola major.

### INTRODUCTION

The execution of successful eradication programmes was a challenge to all countries, but for those which in 1967 had only just begun to develop national infrastructures for health, transport and communication it presented a staggering problem. Ethiopia, with a population of 25.5 million (in 1970), was by far the largest and most populous of countries in this category. Across the Red Sea lay the much smaller states of Yemen (population, 4.8 million) and Democratic Yemen, with its sparse population of 1.5 million (Fig. 21.1). The problem was complicated by civil strife, which was present in all 3 countries either at the beginning or during the course of the Intensified Smallpox Eradication Programme.

In 1967, smallpox was considered to be endemic in both Ethiopia and Yemen; Democratic Yemen, which had reported no cases since 1961, was provisionally categorized as smallpox-free. Because health services were sparse and so few persons were routinely vaccinated, it was feared that the incidence of smallpox in Ethiopia and Yemen might be among the highest in the world;

also, the smallpox-free status of Democratic Yemen had to be regarded with some scepticism.

Recognizing that effective national eradication programmes would take time to establish, WHO began to explore the possibility of developing such programmes in each of the 3 countries as soon as the Intensified Programme was launched in 1967. Four years elapsed, however, before eradication activities had been established in all 3 countries. Plans for a programme in Yemen had been discussed by government and WHO staff as early as 1959, a plan of operations had been signed in 1961 and some vaccine had been provided. However, a civil war broke out which lasted 5 years, and little could be achieved until 1969, when a revised plan of operations was agreed on and a special smallpox eradication unit created within the Ministry of Health. Democratic Yemen embarked on a programme in 1970 and, finally, in 1971, Ethiopia followed suit—the last of the countries which had endemic smallpox in 1967 to participate in the Intensified Programme.

The programmes were each very different in character and operated independently of

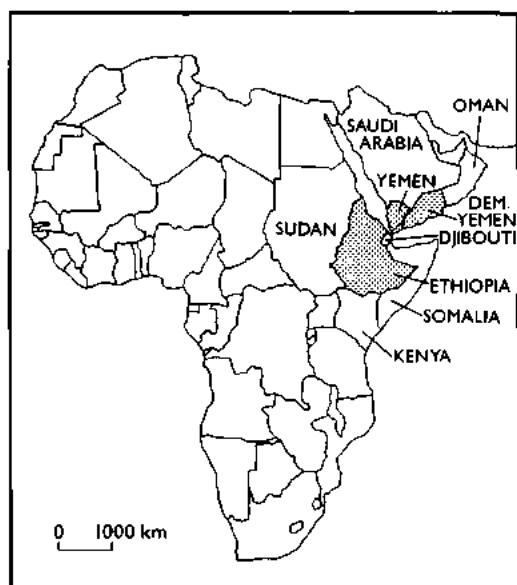

Fig. 21.1. Horn of Africa and adjacent countries.

one another. Epidemiologically, they were also distinct. Despite their geographical proximity, none of the 3 countries is known to have imported cases from either of the others after 1967.

Yemen began a systematic vaccination campaign in 1969 in urban districts and areas accessible by road. After little more than a year, during which 1 million vaccinations were performed, the campaign quickly deteriorated to the point that 5 years elapsed before another million persons were vaccinated. After the programme had begun, only 29 poorly documented cases were recorded in 1969, and none thereafter. From 1971 to 1977, specimens were obtained from 26 suspected cases but none showed evidence of variola virus. Although WHO provisionally reclassified Yemen as a non-endemic country in 1970, this decision was grounded primarily on the absence of reported cases; little other information was available. Because the reporting system was poor and surveillance all but nonexistent, the true status of smallpox remained uncertain until 1978. In that year, a carefully conducted national survey confirmed the absence of smallpox during recent years and suggested that the disease had indeed been absent since 1969.

Between 1970 and 1972, Democratic Yemen conducted an extensive vaccination campaign in and around Aden, the capital

city, and in 1973 extended it to other parts of the country. Surprisingly, only 1 case of smallpox was reported, in 1968, but this report was subsequently retracted, it being alleged that the case had been one of misdiagnosed chickenpox.

Ethiopia's participation in smallpox eradication did not begin until 1971, and up to 1975 the government gave it limited support. Two factors were primarily responsible: (1) national and international malaria eradication programme staff had initially opposed undertaking a programme which they believed would adversely affect their own activities; and (2) when the smallpox eradication programme finally began, it was discovered that only the mild variola minor form was present in Ethiopia, and among the many health problems confronting the government, this disease was not of major consequence. During the first 4 years of the programme, fewer than 100 Ethiopian health personnel, WHO staff and international volunteers, travelling mainly on foot and on muleback, struggled desperately to contain widespread and persistent smallpox. The task was made more difficult by the wide dispersal of the population, more than half of whom lived more than a day's walk from any sort of road in extraordinarily rugged terrain; by a rudimentary governmental infrastructure; and by a dearth of health facilities and manpower. Continuing civil war, hostile groups who resisted vaccination, famine and flood further complicated the effort. Yet, surprisingly good progress was made with the limited resources available. However, smallpox persisted stubbornly throughout vast rural areas, in contrast to the situation in Yemen, in which control measures in the few urban areas were quickly succeeded by the interruption of transmission in the country as a whole. Following the eradication of smallpox in Asia in 1975, greater resources could be made available to Ethiopia, and the new revolutionary government gave substantial additional support. An intensified programme with more adequate resources succeeded in interrupting transmission in August 1976.

The 3 national programmes are described in this chapter in chronological order of commencement, beginning with a brief account of activities in Yemen and Democratic Yemen and concluding with a more detailed description of the Ethiopian programme, which was one of the most difficult, complex

and imaginative of any national eradication campaign.

In this chapter, the spelling of Ethiopian geographical names adopted by the Ethiopian Mapping Agency in 1978 has been followed (Tekeste et al., 1984).

## YEMEN

Yemen, the most densely populated country in the Arabian Peninsula, is situated on an ancient route used by pilgrims, many of them from Asia and some from Africa. After travelling by sea to the port of Aden, 100 kilometres to the south of Yemen, or to other ports on the Arabian Peninsula, or overland, many pilgrims passed through Yemen on their way to Mecca.

The country has an area of 195 000 square kilometres and consists of 3 different geographical regions. The first is a hot arid semi-desert strip, 30–70 kilometres wide, extending along the shores of the Red Sea and inhabited, in 1967, by perhaps 20% of the population, many of African origin. The second area, inhabited by 75% of the population, is a high plateau, about 100 kilometres wide, with densely populated river valleys and scattered villages among rugged mountains. The third area, in the east of the country, is a sparsely populated arid desert in which, in 1967, not more than 5% of the population lived.

Until 1962, when it became a republic, Yemen had been ruled by feudal tribal leaders and was largely isolated from the outside world. According to the first census, taken in 1975, 5.2 million persons were living in the country, and an estimated 1.2 million were working abroad, mainly in Saudi Arabia. Less than 1000 kilometres of roads connected the 3 main towns, Sana'a (population, 100 000) and Taiz (population, 30 000) in the mountains and Hodeida (population, 50 000) on the coast. Most of the population lived in an estimated 15 000 villages, the majority of which could be reached only on foot or on muleback.

During the rule of the tribal leaders, neither health nor educational facilities had been widely developed and such facilities as did exist were primarily confined to the 3 main towns. When the country became a republic in 1962, efforts were made to introduce a modern form of central government, but they were severely hampered by

5 years of civil war. In 1967, more than 90% of the population was illiterate and few people had access to either curative or preventive health services. As recently as 1978, 70% of the 162 districts in the country had no health facilities whatsoever.

Little is known about smallpox in Yemen, there having been no national reporting system until 1975. However, because of the relative isolation of the population, outbreaks were probably infrequent in much of the country. Data from what had been the Protectorate of South Arabia, which included the port of Aden, now the capital of Democratic Yemen, show few or no cases and very few deaths in recent decades, until 1957, when 65 cases with 19 deaths were recorded. The source of infection was reported to have been Pakistan. Outbreaks continued in the Protectorate between 1957 and 1961, and smallpox may well have spread from Aden to Yemen, in which an epidemic started in 1957 or 1958 and continued for several years. It was said to have resulted in not less than 30 000 cases and 18 000 deaths. Assistance from WHO was requested and a team was sent to investigate in June 1959. The team found no active cases in Sana'a, the capital city, but noted large numbers of persons with facial pockmarks. A report from a village of 800 inhabitants stating that only 200 of them had survived the epidemic was indicative of its severity. The evidence, such as it is, suggests that a severe epidemic of variola major had occurred among a population which had experienced little smallpox in recent decades.

During succeeding years, some vaccine was provided by WHO and through bilateral assistance. Vaccination was made available in hospitals in the 3 major towns and at the 20 or so health centres when outbreaks occurred. However, not more than 15 000 or 20 000 individuals were vaccinated each year. In 1962, with assistance from WHO, a national vaccination campaign commenced. Forty vaccinators were recruited and trained; the population of Sana'a was vaccinated in a house-to-house campaign, but thereafter these activities diminished with the gradual intensification of civil strife. Reports obtained during the certification procedure in 1978 suggest that the epidemic of variola major subsided in 1963. WHO was officially notified by Yemen of the occurrence of 5 cases of smallpox in 1964, of 1 case in 1966 and of 3 in 1967, but nothing more is known of these cases or where exactly they occurred.

Reporting at that time was not good and WHO did not endeavour to elicit more complete information about cases until the Intensified Programme was well under way.

In 1967, Yemen was provisionally classified by WHO as an endemic country with the expectation that an effective surveillance programme would probably reveal many hundreds, if not thousands, of cases. Because one of the principal routes of the Mecca Pilgrimage passed through it, Yemen constituted a potential focus for the spread of smallpox to Africa and other countries of Asia. The early initiation of an eradication programme was therefore thought to be vitally important. However, a *coup d'état* in 1967 and continued fighting between republican and royalist forces delayed the start of the work.

In 1968, discussions with government officials led to the approval of a plan of operations for a WHO-supported programme, to begin in July 1969. WHO agreed to provide a medical officer, vaccine, vehicles and a per diem allowance for national staff travelling in the field. In the course of the following decade WHO provided some US\$313 000 in support of the programme (about US\$0.06 per head of population), as well as 3 million doses of vaccine (Table 21.1). The government agreed to provide a counterpart medical officer, 53 vaccinators and 20 auxiliary staff for a 3-year national vaccination campaign during which it was planned to vaccinate 4 million persons (Table 21.2). The development of surveillance was considered an essential component of the plan although

Table 21.2. Yemen: number of vaccinations performed and number of reported cases of smallpox, 1967-1975

<sup>a</sup> According to plan of operations (1968) for mass campaign.

it received little attention from the programme staff.

Headquarters were established in Sana'a under the national programme director, Dr M.K. Al Aghbari, and in July a WHO epidemiologist arrived. Because of the paucity of health staff and facilities, the smallpox eradication programme was envisaged as one which would lay the foundation for other national communicable disease control activities.

A house-to-house vaccination campaign began in October 1969 and at first progressed reasonably well, with assessment showing more than 90% coverage. By the end of the year, 119 752 residents of Sana'a and 192 surrounding villages had been vaccinated, 25% of them for the first time; 80 000 people were vaccinated in other parts of the country. In 1969, 29 cases of smallpox were officially reported by the government to WHO, although at a WHO regional smallpox eradication seminar held in November of that year, the government submitted a report indicating that 47 smallpox cases had occurred. The WHO smallpox adviser in Yemen was asked to investigate and confirm these cases; he merely reported that he thought they were all cases of chickenpox. It was not long before the reliability of his observations was called into question when, in a quarterly report, he stated that, having examined the staff of the smallpox eradication programme, he had been able to ascertain that none were "carriers" of the disease. The quality of surveillance in Yemen did not improve materially thereafter.

In January 1970, when vaccination could be more readily performed than during the intolerably hot summer months, the vaccination campaign shifted to the coastal strip (Fig.

Table 21.1. Yemen: WHO support provided to the smallpox eradication programme, 1967-1979

Total	313 113	3 011

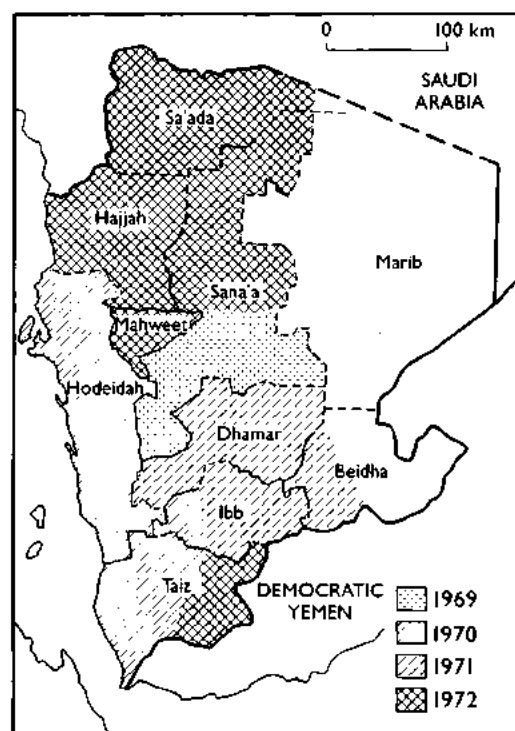

Fig. 21.2. Yemen: progress of the smallpox vaccination campaign, 1969–1972.

21.2). Three vaccination units, each equipped with a vehicle and consisting of a national supervisor and 8 vaccinators, proceeded systematically through the area performing house-to-house vaccination. Staff from the local health services, where such existed, worked with the teams in the expectation that they would continue maintenance vaccination after the teams had left. Each vaccinator averaged about 140 vaccinations a day. An assessment team checked vaccination takes and coverage 1 week later. By the end of the year, more than 800 000 people had been vaccinated.

Towards the end of 1970, the vaccination campaign began to deteriorate. Dr Al Aghbari was asked to assume direction of all preventive services for the Ministry of Health and was therefore obliged to spend less time in the field; project vehicles broke down more often and the field staff began to take increasingly frequent and extended holidays. The WHO adviser rarely left the capital city, and in March 1971 his assignment was terminated.

During the whole of 1971, only 290 000 persons were vaccinated; the level of coverage was unknown because assessment had ceased.

The few reports of smallpox received were seldom investigated; the cases that were examined were diagnosed as chickenpox or dermatitis. The vaccination campaign was gradually extended to most other areas of the country and finally concluded in April 1973, although the inhabitants of most rural areas throughout the north and east remained unvaccinated. Only 231 000 persons were vaccinated in 1972, 45% of them for the first time. From the campaign's inception to its conclusion, the staff succeeded in vaccinating only about 2 million persons—less than half the estimated population. Of this number, nearly 300 000 were vaccinated by teams of the Swedish Save the Children Foundation, who were then providing health services in coastal areas of the country.

The government was dissatisfied with the programme and repeatedly requested the WHO Regional Office for the Eastern Mediterranean to assign another full-time WHO epidemiologist. This request was not met until April 1973, when the former WHO smallpox adviser in the Sudan, despite an unsatisfactory performance there, was transferred to Yemen. In addition to dealing with smallpox, he was made responsible for developing a preventive medicine section in the Ministry of Health and creating a health statistics unit.

About the time of his arrival, the systematic vaccination campaign was terminated and the teams were disbanded. Vaccination continued to be offered through existing health facilities. However, of the 170 000 recorded vaccinations in 1973, 60% were reported to have been given to adults who required international certificates of vaccination in order to leave the country.

None of the health units provided weekly or monthly reports of smallpox cases nor did they submit reports on other diseases. When suspected cases of smallpox were notified, national staff or the WHO epidemiologist investigated them and sent specimens to one of the WHO reference laboratories. In all, 26 specimens were submitted during the 7-year period 1971–1977. None contained poxvirus.

In 1975, a monthly communicable diseases reporting system was at last introduced and reports of smallpox and chickenpox were carried by hand to the capital. This was intended to facilitate investigation by the newly created Department of Preventive Health Services, consisting of a national medical officer, the WHO epidemiologist and

a clerk. Most of the reports received were from the 3 major towns. Five suspected cases of smallpox and 79 cases of chickenpox were reported in 1975 and 2 suspected cases of smallpox and 88 cases of chickenpox in 1976. None of them was confirmed to be a case of smallpox.

From 1970 to the end of 1977, neither WHO Headquarters staff nor the WHO regional smallpox adviser had devoted much attention or effort to the programme in Yemen. Smallpox eradication in other parts of the world commanded a higher priority. Because no confirmed cases of smallpox had been reported from Yemen since 1969 and none was being detected among the numerous pilgrims or Yemeni workers who travelled to Saudi Arabia and to other countries, WHO staff were cautiously hopeful that smallpox transmission had been interrupted.

By the autumn of 1977, when smallpox had been eliminated in Ethiopia (see below) and its interruption in Somalia was imminent, a more detailed appraisal of the situation in Yemen was considered to be essential. A WHO smallpox consultant who visited the country in September 1977 found large numbers of refugees from Ethiopia and some from Somalia living in villages along the coastal desert strip. Few had vaccination scars. An extensive vaccination campaign and search for cases were subsequently initiated in this area, but no cases were found.

In December 1977, another WHO consultant travelled through the highland areas, and, although he found no cases, he discovered that only people living in the larger towns and along the principal roads had been vaccinated during the campaign.

Many of the more remote villages had not been visited by programme staff or vaccination teams for 6-8 years. If variola minor had been imported—from Ethiopia, for example—he believed that it might still be present, spreading slowly through sparsely settled areas, as had been the case in Ethiopia. Accordingly, it was deemed essential to conduct a thorough country-wide search for cases.

From June 1978 to the end of March 1979, a search programme under the direction of an experienced WHO epidemiologist, Mr Robert Steinglass, was conducted by Yemeni staff assisted by personnel of the Swedish Save the Children Foundation and Peace Corps volunteers from the USA, who were engaged in other health programmes in Yemen at that time. Three surveillance teams, each consisting of a team leader, 1 or 2 surveillance workers, a driver and locally hired temporary staff searched 146 of 162 districts and 920 villages and towns with a population of more than 500 persons. In all, 116 184 persons were examined in villages and towns whose total number of inhabitants amounted to 897 488—i.e., 13% of Yemen's resident population. Four hundred and eighty reports of illness with rash and fever were investigated; 43 specimens were submitted for laboratory examination, but none showed evidence of smallpox.

Vaccinal immunity was low, as had been expected. Only 23% of children under 4 years of age and only 63% of the population as a whole had vaccination scars (Table 21.3).

Of 2514 persons with the facial pockmarks of smallpox none was younger than 11 years of age and none had experienced smallpox

Table 21.3. Yemen: results of vaccination scar survey, by governorate and by age, 1978-1979

<sup>2</sup> The Governorate of Marib (population 40 896) was not accessible to government staff and thus area-wide search was not possible.

after 1969. Persons with facial pockmarks were found in 95% of the 146 districts and in 72% of the villages. More than 60% had contracted the disease during the 1957-1963 epidemic.

It had been feared that smallpox eradication in Yemen would present a formidable problem; ironically, the last known cases had occurred just before the mass vaccination campaign began in October 1969. Natural immunity conferred by the extensive epidemic of variola major in 1957-1963, coupled with the practice of variolation, apparently served to reduce the number of susceptible subjects to a sufficiently low proportion of the population that transmission ceased. It is possible that undetected importations, notably from Ethiopia, Yemen's nearest endemic neighbour, may have occurred, but if so they terminated spontaneously. Whatever its problems, the programme served eventually to foster an infectious disease reporting system and provided an impetus to a broader immunization programme, which commenced in 1977.

### DEMOCRATIC YEMEN

Democratic Yemen occupies a vast barren area in the south-western part of the Arabian Peninsula, but as was revealed in its first census in 1973, 55% of the country's population of 1.6 million lived in 12% of the land area in and around Aden, the capital. In 1967, Democratic Yemen was considered to be free of smallpox, the last endemic case having occurred in 1960. However, it was thought to be at high risk of importations. Ships carrying Mecca pilgrims from Asia and Africa regularly called at Aden; and travellers as well as refugees, especially from areas of Ethiopia with endemic smallpox, were numbered in the tens of thousands. Accordingly, a WHO-supported programme was planned for Democratic Yemen.

Until it achieved independence in 1967, the area constituting Democratic Yemen consisted of the British crown colony of Aden and a large number of loosely federated independent sultanates and sheikdoms, known as the Protectorate of South Arabia. Over past decades, occasional small outbreaks of smallpox, usually attributed to cases imported by pilgrims, had been reported from Aden. The last officially notified outbreaks occurred between 1957 and 1961, during

which 341 cases with 105 deaths were recorded, primarily in the western part of the country. The outbreaks were said to have resulted from a series of different importations from India, Pakistan and Yemen. They were controlled by mass vaccination. Twenty-four cases of variola minor, which were not officially reported to WHO but were nevertheless recorded in a government document, occurred in 1965 in the eastern part of the country. As in other countries, there were undoubtedly other unreported cases, but in this very sparsely settled area it was difficult for smallpox transmission to be sustained; any importations that may have occurred ceased spontaneously.

Vaccination with liquid vaccine had been fairly extensively practised in the British crown colony of Aden for many decades. In the less populated areas to the east, protection against severe smallpox was more frequently achieved by variolation. The outbreaks of 1957-1961 had occasioned an extensive vaccination campaign in Aden, some 338 000 vaccinations having been recorded between 1957 and 1959. In 1960, freeze-dried vaccine was first made available by UNICEF for a vaccination campaign, but until 1970, it was uncommon for more than 50 000-75 000 persons to be vaccinated each year.

In September 1969, WHO agreed to support an eradication programme, basically a village-by-village campaign to administer smallpox vaccine to all persons and BCG vaccine to those under 15 years of age. WHO supplemented the salary of the national programme director, paid the national staff a per diem, provided vehicles, vaccine and other supplies and equipment, and made funds available for petrol and vehicle repairs. WHO eventually provided about US\$206 000 and more than 1.8 million doses of vaccine in support of the programme (Table 21.4).

The national staff comprised 48 persons, including 32 vaccinators who worked in 4 operational groups, each with 4 vaccination teams consisting of 2 men. The vaccination campaign proceeded on a house-to-house basis and was regularly assessed by a special team. Because of security problems, operations were initially restricted to 3 of the country's 6 governorates that were located in the immediate vicinity of Aden. In September 1971, one of the programme vehicles, carrying 10 vaccinators and the driver, was destroyed by a land-mine, which killed 4 of the vaccinators and injured the others. Under-

Total	206 230	1 815

standably, the staff feared to venture too far from the capital. Not until 1973 did civil disorder subside sufficiently to permit the extension of vaccination activities into all governorates.

As is shown in Table 21.5, the number of vaccinations performed annually from 1970 onwards ranged between 169 364 (1971) and 302 296 (1973). Productivity was not high, each vaccinator averaging about 50 smallpox vaccinations and 10-20 BCG vaccinations a day. This was partly attributable to the difficulty of travelling through the generally rugged mountainous country, with few roads. Assessment figures indicated that the coverage achieved was consistently about 90%, but it took 7 years for a total of 1.5 million vaccinations to be performed, a number approximately equivalent to the population. During this time, some 514 000 BCG vaccinations were also administered.

Despite the strategic location of Democratic Yemen and the apparent risk of importations, no cases were confirmed after 1967. A single case in Aden was reported to WHO in 1968 but the report was later retracted in the belief that the illness had been chickenpox. The absence of known importations can be explained in part by diminished maritime traffic associated with the closure of the Suez Canal from 1967 to 1975 and in part by restrictions on travel imposed by the government after independence in November 1967. Conceivably, outbreaks may have been overlooked since neither a surveillance nor a morbidity reporting system was ever developed. However, extensive surveys conducted during the country's programme in

Table 21.5. Democratic Yemen: number of vaccinations performed and number of reported cases of smallpox, 1967-1975

Year	Number of vaccinations	Number of reported cases
1967	10 830	0

1975	242 881	0

<sup>a</sup> Six months only.

1978 to certify the absence of smallpox failed to detect any person who had been infected with the disease since 1966. These surveys also showed that, in the different governorates, between 76% and 90% of the population had vaccination scars—a high level of vaccinal immunity.

Contrary to expectations when the programme began, Democratic Yemen did not experience problems with smallpox; in retrospect, a special vaccination programme may have been unnecessary. However, the combined smallpox and BCG vaccination campaign did provide a basis for the establishment of a national immunization programme.

## ETHIOPIA

Ethiopia was 6 times larger in area (1.2 million square kilometres), with a population (25.5 million in 1970) more than 5 times greater than that of Yemen, but the problems of geography and population dispersion were similar. Most of Ethiopia's population was widely distributed in small groups of huts scattered across the central highlands (Fig. 21.3) at 1500-3000 metres above sea level. Rugged mountains and deep ravines made travel extremely difficult throughout this area, and impossible during the rainy season, from June to September. At the periphery of the country were lowland areas in the west and south-west, with a fertile and more populated savanna grassland. Nomads roamed the vast Danakil and Ogaden deserts to the east, moving freely across the unmarked borders with Somalia and the French Territory of the Afars and the Issas (later Djibouti). Less than 10 000 kilometres of all-weather roads connected the few scattered cities and towns. Health facilities and trained health

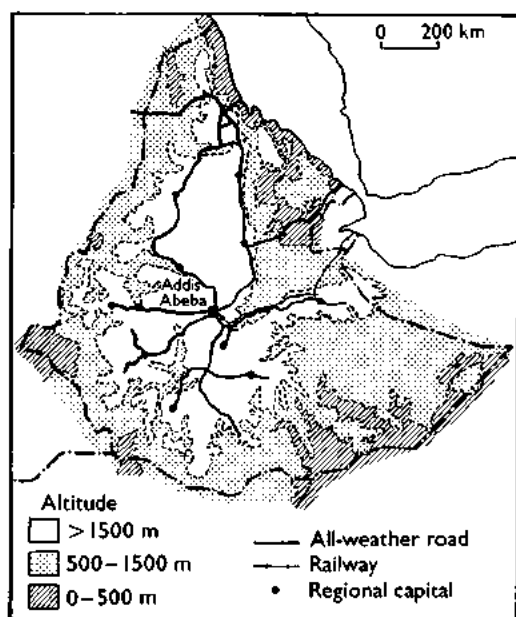

Fig. 21.3. Ethiopia: topography and road system.

staff were few; vaccination was all but unknown to most of the population, but variolation was widespread. Several hundred cases of smallpox were reported each year, but in 1967 it was surmised that thousands of cases must be occurring.

Throughout the world, experience had shown that smallpox transmission was not readily sustained in sparsely settled areas. Elimination of smallpox from urban centres and the accessible, more populated rural areas usually resulted in the disease dying out spontaneously in the more remote parts of a country. In Ethiopia, this did not happen. Here, among a dispersed, thinly settled population, the global eradication of smallpox came nearest to being thwarted, as an unparalleled array of problems and catastrophes continually hampered the programme. Nearly 6 years elapsed after the campaign had begun before the last outbreak was finally discovered and contained, in August 1976.

A detailed account of the programme is presented in the book *Smallpox Eradication in Ethiopia* by Tekeste et al. (1984), from which most of the data in this chapter are drawn.

### Background

Ethiopia, in 1967, was one of the world's least developed countries, and until 1974 it

was a monarchy with numerous feudal landlords. The infrastructure of services for health, education, transport and communications was rudimentary except in the northern province of Eritrea, in which a number of roads and health centres had been built during the Italian and British administrations.

Administratively, the country was divided into 14 provinces (which, after the 1974 revolution, became 15 regions), each with a governor, who was usually a member of the royal family. Each province was subdivided into *awrajas* (102 in the country as a whole) and these, in turn, into *woredas* (539 all told), each with its appointed governor or administrator. At the local level, the feudal, often absentee, landlord was the acknowledged headman, but he was frequently indifferent and sometimes hostile to higher government authority. To obtain assistance with the programme at each administrative level a special letter requesting cooperation had to be prepared by a superior and taken by messenger to the official concerned.

No census had ever been taken but it was thought that no more than 2 million of the estimated 25.5 million population lived in about 200 towns and villages of 500 or more persons. In the rural areas of the plateau, the houses were widely scattered. There, the smallest traditional unit, sometimes referred to as a village, was the *mender*, consisting of up to 100 houses occupied by one or more related families. Fifty or more *مندرس* comprised a *deber*, which included the membership of a single church. After the 1974 revolution and nationalization of the land, workers' co-operatives, called "farmers' associations" or "urban dwellers' associations", were created and village areas were defined. The villages, however, were unlike those in most other countries in that they usually extended over large areas, the distance between houses often ranging from a few hundred to a thousand metres. In the extensive eastern and southern scrub desert areas, which comprised half the country, nomadic groups with ethnic ties to the neighbouring French Territory of the Afars and the Issas and Somalia wandered freely, not infrequently crossing open borders between the countries. In the south-west were tribal groups whose way of life was little more advanced than that of a Stone Age culture.

Roads of any type were few; more than 85% of the population lived further than 30 kilometres away from the nearest all-weather road (Ayalew, 1982). Travel from place to

place during the dry season was largely on horse- or muleback or by foot. When torrential rains occurred in the highlands, between June and September, large areas became completely inaccessible. Communications were poor: an unreliable, frequently unusable, telephone service linked the capitals of provinces, and the postal service was deficient.

Language presented a further problem. The people of Ethiopia consisted of 10 major ethnic groups speaking 70 languages and dialects. Frequently, programme staff had to communicate successively through two or three different interpreters to question villagers about the existence of smallpox and to explain the unfamiliar practice of vaccination. Some people were reasonably receptive, but refusal and sometimes active resistance were encountered among many who lived in the highland areas in the north and central parts of the country. Not surprisingly, smallpox proved to be particularly tenacious in those areas.

Health personnel and facilities in 1967 were concentrated in Addis Abeba, the capital, and in Eritrea. The largest proportion of the government's health budget was allocated to curative services, to which not more than 5% of the population had access. Government records for 1967 show a census of 84 hospitals and 64 health centres and a total of 362 physicians and 2800 other health staff. For 40% of the population, a journey of 3 days or more, and for another 30%, a journey of 1-2 days, was required to reach the nearest health unit. Personnel engaged in the administratively separate malaria eradication programme were far more numerous than the national health services staff. In all, 8000 malaria eradication staff were distributed over about one-third of the country. They were concerned only with malaria and were supported under a bilateral assistance programme.

Protection against smallpox was often provided through variolation. This was usually performed by the head of a household among family members after cases began to occur in the vicinity. The Afghan type of professional variolator, who travelled widely and preserved scabs and pustular material over long periods of time, was uncommon. Data on the number of smallpox vaccinations performed annually before 1971 are not available but estimates indicate the total to be less than 500 000. Most of them were performed in

hospitals and clinics; a few were given by an "Anti-epidemic Service", a small mobile unit which vaccinated people in and around Addis Abeba when outbreaks were reported. The vaccine, which had been produced at a government laboratory in Addis Abeba since 1953, was of the thermolabile liquid variety. In the mid-1960s, however, the preparation of a freeze-dried vaccine began, but this could not be tested for potency owing to a lack of fertile eggs. When it was eventually examined by a WHO reference laboratory, it was found to be unsatisfactory. In 1970, freeze-dried vaccine was provided by WHO and vaccine production in Addis Abeba ceased.

Little is known about the prevalence, extent and severity of smallpox before 1971. Epidemics with high mortality were said to have occurred every 10-30 years during the 19th century. Annual statistical compilations that date from 1931 show as many as 2832 cases in 1956 but comparatively few in most years. The cases that were reported were among hospitalized patients in the few urban

**Plate 21.1.** A variolator in Ethiopia obtaining pustular material from a patient (lying) and inoculating it into the arm of a healthy recipient (standing). Variolation was usually performed by one of the elders in a family and was widely practised throughout Ethiopia. The last known patient in Ethiopia (August 1976) developed illness following variolation. (Detail from a painting by Zerihun Yetmgeta presented to WHO by the Government of Ethiopia.)

### Variolation and Receptivity to Vaccination

Smallpox was widely recognized and feared by the different ethnic groups throughout Ethiopia, each of which, in the absence of vaccination, dealt with it in a different manner. Among the Amharas, who largely populated the central zone provinces and Shewa, and among the nomads of the eastern desert areas, protection was obtained through variolation, which was practised widely when outbreaks occurred. Many Amharas resisted vaccination in favour of variolation and religious ceremonies that consisted in decorating the dwelling of a patient with fresh green leaves, grasses and flowers and in burning incense. Sheep, goats and hens of different colours were sacrificed and ritual play-acting and singing were performed to induce the disease to take a mild form. Other groups had other practices and rites. When smallpox occurred, the Nuers, a Nilotic tribe living near the Sudanese border, performed a ceremony in which a prophet would lead the people to a river where goats were sacrificed to the "mother of gods", who was thought to live in the river; in a ceremony of joy, the assembled crowd would then bathe in the river.

For reasons which are unclear, most ethnic groups in the south and east of the country readily accepted, indeed actively sought, vaccination whether or not they performed variolation. Among Galla groups, who inhabited large areas of provinces in the south-west and south-east, people returned many times for vaccination, and many villages reported falsely that outbreaks were occurring in order to induce the teams to visit. In this area, it was not uncommon for teams to discover crudely scribbled notes left along trails requesting visits to villages as distant as 40-50 kilometres.

centres. There is no information on the number of deaths. After 1971, when the eradication programme began and more complete data became available, only the mild variola minor form of smallpox was found. Variola major had disappeared, but it is not known when this occurred. Variola minor was documented as early as 1958, but as recently as 1964 a smallpox outbreak with a high case-fatality rate typical of variola major was reported by a health officer in the central highlands.

### Delays in Launching an Eradication Programme

At the inception of the Intensified Smallpox Eradication Programme in 1967, Ethiopia was considered to be strategically important as an endemic country. The neighbouring areas of the French Territory of the Afars and the Issas, Somalia and the Sudan were thought to be free of smallpox. Kenya, with an extensive network of health services and a more complete notification system, was reporting fewer than 200 cases a year. If reinfection of adjacent countries was to be averted, a programme would have to be started in Ethiopia as soon as possible.

Government officials stated, however, that they were not interested in undertaking a

smallpox eradication programme and could not do so because so many resources were already committed to malaria eradication. They reasoned that one eradication programme must be as expensive as another, a belief encouraged by expatriate malaria advisers. Given that the Ethiopia malaria eradication programme was then disbursing more than US\$8 million a year, primarily from bilateral contributions, and that it employed 8000 workers, their apprehension was understandable. The government authorities did not appreciate that a smallpox eradication programme was far simpler, cost much less and required far fewer personnel than a malaria eradication programme. Moreover, WHO staff believed that smallpox eradication in Ethiopia might be combined successfully with other health activities then being considered, including a BCG vaccination programme in urban areas and a proposed yellow fever vaccination campaign which the Federal Republic of Germany was expected to support. The most extensive resources available were those of the malaria eradication programme itself. It was felt that much could be accomplished if its directors would permit the thousands of malaria workers to serve as smallpox surveillance agents and to vaccinate those encountered during their regular house-to-house visits. In addition, several

projects staffed by United States Peace Corps volunteers were then in operation in Ethiopia and it was understood from United States government officials that they would be receptive to a request to provide manpower to health-related projects.

WHO smallpox eradication staff believed that a suitable, economically feasible and acceptable plan for at least a control programme, if not for eradication, could be developed. To do so would require appraisal and discussion in Addis Abeba of potentially available resources and of the cost and options for the conduct of such a programme. Repeated proposals were made to the government that WHO regional and Headquarters staff should make an exploratory visit, but for nearly 3 years these proposals were firmly declined. Initially, this reaction was difficult to understand because most governments were more than willing to discuss possible options, whether or not they were inclined to undertake a programme. Gradually, however, it became known that the United States malaria eradication programme adviser and his Ethiopian counterpart had persuaded the Minister of Health that a smallpox eradication programme would fatally compromise the malaria eradication campaign, which was then making little progress. They advised that, under the circumstances, his best approach would be to refuse to receive WHO smallpox eradication staff, even for exploratory discussions.

The impasse was not readily resolved. The strategy and the projected order of magnitude of needs for smallpox eradication were discussed in Geneva at the World Health Assembly with Ethiopian government officials and malaria advisers from the USA, with bilateral assistance staff in Washington and with malaria staff at the United States Center for Disease Control—all to no avail. An indirect approach to the government was planned when Dr George Lythcott, senior adviser to the United States-aided western and central African smallpox eradication programme, was invited to speak about that programme at a meeting of the Organization of African States in Addis Abeba. Having been briefed by WHO staff and being prepared to hold informal meetings with Ethiopian government officials, he was about to leave for Addis Abeba when United States officials abruptly and without explanation cancelled his trip.

Nearly 3 years had elapsed when, inexplicably, in October 1969, the government responded favourably to yet another proposal for an exploratory visit. Dr Ehsan Shafa, then Regional Adviser on Smallpox Eradication at the WHO Regional Office for the Eastern Mediterranean, and Henderson flew immediately to Addis Abeba. The response to the proposed visit had been sent by a subordinate when the Minister and Secretary of Health were absent on a trip abroad. They were not pleased, on their return, to find the WHO team awaiting them; they made it clear that Ethiopia's attitude had not changed. They did agree, however, that Henderson and Dr Shafa could devote 2 weeks to the preparation of a plan which the government would consider. In view of WHO's budgetary limitations and the obvious antipathy of the government, it was apparent that whatever programme might be devised would have to be a modest one. The malaria eradication programme's considerable resources in manpower and transport offered a potential building block, but its director declined to co-operate in any way. There were no other immunization programmes and little assistance could be expected from the few existing health units. However, tentative offers to provide volunteers were made by the USA and Japan. Among the many officials to whom Henderson and Dr Shafa spoke was Dr Kurt Weithaler, then serving as director of

BY COURTESY OF D. A. HENDERSON, 1971

**Plate 21.2.** Kurt L. Weithaler (b. 1919), an experienced health administrator, served as the senior WHO adviser to the Ethiopian smallpox eradication programme from 1970 to 1976.

the hospital for the Emperor's Imperial Guard. Dr Weithaler, an Austrian, had been employed by the government for more than a decade, was widely known in government and medical circles, served as a member of the Health Minister's advisory panel the General Medical Board—and was a friend of the Emperor. He expressed considerable enthusiasm for the programme and intimated that he might be persuaded to serve as WHO's senior adviser. The draft plan of operations was presented to the Minister on a Saturday for consideration that weekend and a decision on Monday. He expressed little interest. Meanwhile, unbeknownst to the WHO team, Dr Weithaler showed the plan to the Emperor, who agreed that it should be initiated and ordered the Minister of Health to support it.

### The Programme Begins, 1971

The draft plan of operations envisaged: (1) a search for outbreaks and their containment to the extent possible with the available manpower; (2) the development of a simple surveillance programme for the reporting of cases and vaccination by the staff of existing health facilities; and (3) mass vaccination in Ethiopia's few centres of population. It was hoped that, with the limited personnel and equipment that could be provided, smallpox transmission might be successfully interrupted in the accessible areas. It was to be hoped that the disease would then die out spontaneously in at least some of the rural areas. However, since a relatively small proportion of the population lived in accessible areas and since vaccinal immunity was undoubtedly as low as anywhere in the world, the proposition was uncertain. All the same, a less than fully effective control programme was better than no programme at all.

A staff of about 70 was envisaged. The government requested that a senior WHO medical officer should be appointed as "the responsible executive authority", and the energetic Dr Weithaler was recruited to fill the post. It was exceptional in most countries for a person assigned by WHO to serve in this capacity but, in Ethiopia, in which trained personnel were in short supply, such an appointment was considered essential. A WHO epidemiologist was to be appointed for surveillance, and Dr Ciro de Quadros, who

had served previously on the national staff of the Brazilian smallpox eradication programme (see Chapter 12), was selected for this post. The government assigned as the senior national professional Ato Tamiru Debeya, a respected and able person who retained this responsibility through 1975. His title was that of sanitarian but, in Ethiopia at that time, such persons had a broad public health training and served as administrators for many public health programmes. Twelve other workers were to be assigned to the headquarters office—3 drivers, 8 office staff and a most competent locally recruited WHO administrative officer, Ato Tefari Seyoum. For assignment to the field, the government agreed to provide 21 staff, health officers or sanitarians, who would work with volunteers from the USA. The health officers played an exceptionally important role; they were graduates of a recently established 4-year course of study in the health sciences which was designed for students who had completed secondary school.

Ethiopia's financial commitments consisted only in paying salaries of its health officers and sanitarians, all of whom were transferred from other programmes, and meeting the cost of office accommodation. WHO provided all supplies and equipment and covered the cost of transport, as well as

E. SNAJJA, c. 1973

**Plate 21.3.** Ciro C. A. de Quadros (b. 1940) worked in the smallpox eradication programme in Brazil before joining WHO and the programme in Ethiopia, 1970–1976. In 1977, he became regional adviser for the Expanded Programme on Immunization in the Americas.

the per diem allowances of Ethiopian staff and the salaries of the central office staff. The salaries and expenses of the volunteers were borne by their respective governments. WHO provided, in all, US\$175 562 in 1969-1970, in addition to supplies of vaccine (Table 21.6). Eventually, the Organization was to spend nearly US\$13 500 000 from its regular budget and from contributions made by numerous governments to the WHO Voluntary Fund for Health Promotion and to contribute more than 23 million doses of vaccine. The Ethiopian government spent US\$1 360 546. Additional support, amounting to about US\$1 390 000 was provided, in cash and in kind, through bilateral contributions from Austria, the Federal Republic of Germany, Japan and the USA. The total support to the programme amounted to about US\$0.57 per head of population.

During the autumn of 1970, personnel were recruited, the volunteers from the USA arrived, equipment was delivered, a central office was established, training programmes were conducted, and by mid-January 1971, field operations began. At that time, there were only 3 other countries in Africa in which smallpox remained endemic—the Sudan, Zaire and South Africa. The latter 2 succeeded in interrupting transmission in 1971 (see Chapters 18 and 20).

For a programme in one of Africa's last endemic countries—one of its largest and least developed—the available resources were few indeed. Over the first 6 months, the entire field staff consisted of only 39 persons—the 2

WHO advisers, 2 health officers, 19 sanitarians and 16 United States volunteers. They had only 6 Land Rovers between them, although 11 more were scheduled for delivery that summer. In the interim, it was hoped that vehicles might be borrowed from the malaria eradication programme's large reserve pool of vehicles, which were parked at a training centre south of Addis Abeba. A request was made, but the vehicles mysteriously vanished. The request was denied on the grounds that all vehicles were in use. (It was later learned that they had been transferred to a motor pool in a remote desert area.)

It was decided to concentrate personnel and vehicles in the 4 provinces of the south-western zone: Gamo Gofa, Kefa, Ilubabor and Welega (Fig. 21.4; Table 21.7). Besides being epidemiologically important because they bordered on the Sudan, these provinces had a better health service structure than most, and the people's acceptance of vaccination was generally good. Two additional vehicles and teams were assigned for work in Addis Abeba and the surrounding Shewa Province. One sanitarian was assigned to each of the other provinces to establish a smallpox eradication programme office in or near the office of the provincial medical officer. His duties were to report weekly any cases of smallpox that were discovered, to compile a list of health facilities, and to visit them, by bus or mule, in order to provide vaccine and to encourage them to report cases and to vaccinate. In the 4 priority provinces, these functions were to be undertaken by the teams,

which were also expected to carry out an active search for cases and to contain by vaccination any outbreaks that were found.

To provide encouragement and guidance to the smallpox eradication staff and other health personnel throughout the country, Dr de Quadros, in January 1971, inaugurated the publication of a surveillance report which documented smallpox incidence and conveyed important information and instructions. The report was at first distributed monthly to health personnel and relevant government officials throughout the

country; late in 1974, weekly publication began. The report proved of inestimable value in securing cooperation and support and also served to sustain morale among the widely distributed smallpox eradication staff, who could contact each other only infrequently.

The number of cases that might be discovered when the teams reached the field was a subject of intense speculation. Ethiopia had reported only 197 cases in 1969 and 722 cases in 1970. It was recognized that smallpox was greatly underreported, but the extent of the underreporting was unknown. Although few vaccinations were being performed, variolation had been extensively practised throughout the country and had undoubtedly rendered many persons immune. To obtain some idea of the possible extent of smallpox, Henderson and Dr Shafa, during their visit in 1969, had questioned many health officers, mission health personnel and others, both in Addis Abeba and on a field visit to Welega Province. Surprisingly, few persons reported having seen many cases of smallpox recently and some reported having seen no cases whatsoever for many years. Although the survey was brief and incomplete, it fostered the hope that smallpox might be uncommon in the sparsely settled rural areas and that continuing endemic transmission might be confined primarily to the comparatively few populous areas.

Whatever the smallpox situation may have been in 1969, it differed greatly in 1971 from

### Smallpox Surveillance and Containment in the South-west Zone in 1971

One volunteer, Mr Vincent Radke, has described his own initial surprise at the magnitude of the smallpox problem and the necessary adaptations in procedures which field staff had to make. During the training programme, the surveillance teams had been instructed to undertake a planned series of trips through the province for which they were responsible. They were to visit health centres and schools, where these existed, as well as village leaders and, in showing the WHO smallpox recognition card, were to inquire about possible smallpox cases. Any reports were then to be investigated. In the first classroom Mr Radke visited in Kefa Province, he obtained so many reports of cases in so many different villages that he did not bother to visit the other classrooms but went immediately to investigate. Village after village throughout many parts of this and other south-western provinces were found to be so heavily infected with smallpox that he and his fellow-workers decided that for some areas, even village-by-village containment vaccination was futile. Instead, they began to try to define the outer limits of the spreading epidemic and to concentrate on vaccination in populations at the circumference of the outbreak area, much as one would fight a forest fire.

what had been expected. The teams began work in mid-January and discovered 278 cases in only 2 weeks; 1493 cases were found in February and 3434 cases in March. This amounted to half the cases being reported throughout the world at that time. Henderson was sceptical that so few field staff could discover and investigate so many cases; he therefore cabled Dr Weithaler and Dr de Quadros, cautioning against recording rumoured outbreaks without due investigation. They were justifiably indignant and replied by cable and letter that the only cases reported were those individually confirmed by the smallpox eradication staff. Dr de Quadros had established a reporting system which was similar to that used in Brazil. A form was completed for each household in which a case was discovered. The form included the name, age, sex and past history of smallpox and vaccination of each household member. Only the cases seen by the surveillance teams and recorded on the forms were reported. The Ethiopian programme, in fact, had the most comprehensive data collection system of any national eradication programme and was the only one in which data were collected from the outset.

Since vehicles were available only to the teams in the south-western zone and Shewa during the first 6 months, it was not expected that the health officers and sanitarians assigned to other provinces would undertake much field work. However, most of them exhibited extraordinary ingenuity in getting from place to place by bus and borrowed

vehicles, by foot and by mule. They, too, discovered and investigated numerous cases of smallpox.

Up to the end of June 1971, the field staff of only 39 persons documented 13 447 cases, more than had been recorded in the whole of India during the preceding year. Meanwhile, the threat that Ethiopia represented to its smallpox-free neighbours became manifest in March, when an outbreak of 46 cases of smallpox, introduced by an Ethiopian cattle herder, was discovered in Kenya. The now evident epidemic smallpox and the concern shown by neighbouring countries served to alarm the government, and from then on the programme began to receive somewhat greater support.

Seasonal torrential rains began throughout the highlands in June and, until September, forced the surveillance teams to restrict activities to populations living along the few all-weather roads. There, in addition to a search for cases, extensive systematic vaccination campaigns were conducted in the towns and cities. In Addis Abeba itself, smallpox eradication staff, with help from the Anti-epidemic Service and 12 secondary-school students, vaccinated 154 000 people over a 2-month period.

It was apparent that the problem in Ethiopia was a major one, requiring far greater resources than were available. Efforts were intensified to find such support. The government agreed to provide some additional staff but, in fact, had few available who could be mobilized except for personnel

of the malaria eradication programme, but a request for the transfer of some of these staff was refused. Programme funds previously destined for countries in the WHO African Region were transferred to Ethiopia, as well as what little remained for smallpox eradication in the WHO Voluntary Fund for Health Promotion. Other Headquarters funds for

1972 were earmarked for the recruitment of another WHO epidemiologist, Dr P. A. Koswara, formerly the director of Indonesia's successful programme. Continuing discussions with the government of Japan led to its commitment to provide 30 transceivers as well as 5 vehicles and 12 volunteers to serve as radio and automobile mechanics. The Austrian government agreed to provide 4 volunteers, and the USA to increase the number of its volunteers.

The end of the seasonal rains and the return of the teams to the field were eagerly awaited. During the rainy season in other parts of the world, smallpox was transmitted much less easily, and with travel restricted, the disease often died out in large areas. Moreover, the number of susceptible individuals was clearly lower than in the previous year because of the extent of the epidemics and the large-scale vaccination-containment activities that had been conducted in urban areas during the rainy season and in rural areas earlier in the year. Any hope that the smallpox problem might soon become more manageable vanished, however. The number of cases discovered totalled 2113 in September and rose each month, reaching 3322 in December.

In 1971, 26 329 cases were recorded, more than half in Shewa and the 4 provinces of the south-west zone, in which reporting was the best (Table 21.8). Cases were detected in 146 of the country's 539 *woredas* in the first half of the year, and in 160 *woredas* in the latter half (Fig. 21.5). In all, 3.1 million vaccinations

were performed, nearly 15 times the number given during the preceding year; yet this figure represented no more than one-eighth of the population. It was clear that a long and difficult task lay ahead.

### The Second Year, 1972

In 1972, more resources became available (Table 21.9). A staff which had grown to 67 by January 1972 rose to 82 by the end of the year as additional volunteers from Austria, Japan and the USA joined the programme. In November 1971, a special meeting was held with the provincial medical officers to explain the programme to them and to solicit their support. Gradually they, as well as staff attached to health centres, took an increasing interest in the programme and made substantial contributions. WHO assigned an additional epidemiologist—Dr G. P. Marchenko, who was transferred from the programme in Pakistan. A fleet of vehicles numbering 27 in January increased to 49 by the end of 1972, making the surveillance staff far more mobile. The transceivers, of which half were based at provincial capitals and the other half mounted on vehicles, greatly facili-

tated communication. Dr Weithaler and Dr de Quadros sought additional help wherever it could be found. Thus ensued, in successive years, a large number of cooperative undertakings with private and public sector groups, including the personnel of a leprosy control programme, mission groups, scientific expedition staff and emergency relief workers, all of whom were supplied with vaccine and asked to report cases of smallpox and to perform vaccinations. Volunteers were also found among visiting health professionals, a number of whom served the programme for many months without salary, receiving the same per diem as Ethiopian staff.

Major difficulties had, however, become more apparent. Only variola minor was found and mortality was low: in 1971, for example, only 530 deaths were recorded (a case-fatality rate of 2.1%). Even in the acute phase of illness, patients experienced so few symptoms that they were able to travel easily, spreading the disease to contacts. A second problem was widespread resistance to vaccination among the two ethnic groups, the Amhara and the Dorsey, which constituted most of the population of the central zone, northern Shewa and some adjoining areas. A third

<sup>a</sup> Status as at end of each year.

problem was the widespread practice of variolation, to which, in 1971, more than 3000 cases (12% of the total) were attributed. Many more persons than this were known to have been variolated but, as was the practice in Afghanistan (see Chapter 14), only those who developed a generalized rash in addition to a lesion at the site of inoculation were counted as cases. Lastly, it had become apparent that such maps as were available were very incomplete and often erroneous. Accordingly, the teams found it necessary to prepare their own sketch maps of each *awraja* and its subdivisions, the *woredas*, in order to identify the locations of outbreaks.

By the summer of 1972, the control of smallpox had begun to improve. During the first 6 months of 1972, the number of reported cases had remained as high as in 1971, with one-third of the 538 *woredas* notifying cases. During the rainy season, the number of reported cases fell steeply, as it had in the same period of the previous year. Thereafter, the number of cases recorded monthly remained below 1000 despite an increasingly comprehensive surveillance system. The total number of cases reported in 1972 was 16 999—nearly 10 000 fewer than in 1971. Most of this decrease was accounted for by a sharply diminished incidence in the last 4 months of the year, 2363 cases being reported in this period compared with 10 725 in 1971. During 1972, 3.2 million additional persons were vaccinated.

Progress in the 4 provinces of the south-west zone was highly encouraging, although not unexpected because resources had been concentrated there. Containment vaccination throughout this zone had been extensive because of the widespread outbreaks and was readily accepted, indeed actively sought, by most of the population. There were, however, some tribal groups which caused difficulties. As was reported by some of the smallpox eradication staff, "...many workers were suffering at one time from human bites" (WHO/SE/72.48, Tilahun et al.). By the end of 1972, vaccinations equivalent in number to more than half the estimated population had been performed in the 4 provinces and the number of reported cases of smallpox in 1972 fell by nearly two-thirds. In 2 provinces, Illubabor and Welega, transmission was interrupted by the end of the year.

A rapidly declining incidence in Eritrea and Tigray Provinces was most unexpected, however. These provinces, whose population

was nearly as large as that of the 4 provinces in the south-west, had each been assigned only one sanitarian—Ato Tadesse Fissehay and Ato Worku Gebre Selassie, respectively. Both were dedicated and imaginative workers and proved successful in overcoming extraordinarily difficult problems. Eritrea, although endowed with substantially more extensive health facilities, communications and roads than other provinces of Ethiopia, was torn by civil war. Large areas were periodically cut off so far as road travel was concerned, while other areas were completely inaccessible to government authorities. On assuming responsibility for the programme, Ato Tadesse Fissehay, contacted all health units to establish a reporting network and to encourage them to vaccinate both patients and nearby inhabitants. As a native Eritrean, he was able to contact dissident groups to explain the programme and obtain their cooperation. Accordingly, he was usually able to travel throughout the province, despite the civil war, to investigate and contain outbreaks. He contained 65 outbreaks with 487 cases in 1971, and 10 outbreaks with 86 cases in 1972. The last endemic case in Eritrea occurred in December 1972. Only 2 importations, resulting in 3 cases, were subsequently discovered in 1973. Tigray, which was more mountainous and had fewer resources, presented a different type of problem. There, Ato Worku Gebre Selassie persuaded the able and widely respected governor to lend his per-

BY COURTESY OF D. A. HENDERSON, 1972

**Plate 21.7.** Smallpox staff in Addis Abeba, 1972. Left to right: James Lepkowski (a United States Peace Corps volunteer), Ashagre Hailemariam, D. A. Henderson, Tadesse Fissehay, and Tarekegn Hailu.

sonal support to induce health and other civil authorities throughout the province to co-operate in a search for cases and their containment. Travel was not then hampered, and by the end of 1972 transmission had been interrupted in this province also. Importations were to occur in 1973 and 1974, resulting in 17 and 30 cases respectively, but both outbreaks were effectively contained. Except for these imported cases, the northern provinces remained free of smallpox after 1972. The early interruption of transmission in Eritrea and Tigray was fortunate because the intensity of civil strife in this area heightened significantly in later years, making it far more difficult to travel freely and to obtain the cooperation of the population.

### A Year of Hope, 1973

In only 2 years the smallpox eradication staff, few though they were, had made remarkable progress, and the programme gained such momentum in 1973 that by the end of the year expectations were high that transmission might be interrupted within the next 12 months. The staff had become more experienced and, during twice-yearly seminar training programmes, had steadily modified and improved surveillance techniques. The staff at health centres were increasingly cooperative and participated more actively in reporting and in vaccination campaigns. In fact, 20% of all cases in 1972 were reported by the regular health services. Problems of transport and radio maintenance and repair were fewer, thanks to the Japanese volunteers; adequate supplies were available for camping and the arduous treks on foot or on muleback.

Surveillance methodology had been evaluated in June 1972 in an imaginative study which provided additional confidence in the approaches being adopted. A surveillance officer, Mr James Siemon, accompanied by a vaccinator, undertook a 14-day search in a remote mountainous *awraja* covering an area of 48 000 square kilometres and with a population of 275 000 (Quadros et al., 1973). No cases had been reported for 6 months. The 2-man team travelled extensively through the *awraja*, mainly on foot, making inquiries about smallpox cases among administrative officials and at the sole health centre and 4 health stations, at 8 schools, and at weekly markets. None of the administrative officials, village leaders or health staff knew of any

cases. However, 5 different persons, at 3 markets and 2 schools, identified a single small outbreak of 8 cases in 3 households. Mr Siemon investigated the outbreak, which was 2-9 hours' walk from each informant, and discovered it to have been caused by an importation from another province. From follow-up surveys, it was confirmed to be the only outbreak then present in the whole *awraja*.

A description of surveillance activities as practised at this time is helpful to an understanding of the programme and how it functioned. In most provinces, 2 surveillance teams were assigned, each team being responsible for an area with a population of 500 000 to 2 million. The team leader prepared a sketch-map and drafted a rough tour plan so that each *awraja* could be visited regularly. In some provinces, this often meant a walking tour of 3 or 4 weeks in just one *awraja* as the team progressed from valley to valley. A team of 2 workers was found to be the most practical because its members could be more readily accommodated locally. For ease of travel, they carried minimal supplies but were given letters by administrative officials to local leaders requesting that they should be provided with food and accommodation. By staying overnight with local leaders, they became better acquainted with the local people and were often able to obtain assistance from them in searching for cases and performing vaccinations. As the programme gradually began to concentrate on the more mountainous central and northern areas, vehicles were less often used because travel by foot and by mule proved more practical and permitted access to more difficult areas. Accordingly, the vehicles available to the programme staff began to be used primarily for transporting teams and supplies to points accessible by road and picking them up again at an arranged rendezvous point after 2-4 weeks. On arrival in the *awraja*, the team visited the offices of the *awraja* and then the *woreda* administrators to inquire whether they were aware of smallpox cases. Because there was little contact between officials and villagers at that time, this procedure was rarely useful in finding cases. However, official letters from the *awraja* and *woreda* officials helped in making contact with village leaders. The team then visited each market, clinic, school and church. Weekly markets were a feature of both rural and urban Ethiopia, and although most of the people attending lived

within 3 hours' walking distance, some travelled for as long as 3 days. For market surveillance, careful planning of the tour was required because markets were held on different days in different villages. Clinics and schools were comparatively rare but, where present, they were often a helpful source of information. Coptic churches, a prominent feature of the mountainous plateau area, convened adults for Sunday services from distances of up to 15 kilometres. Other persons encountered on tour were also questioned about smallpox.

Because the population was sparsely settled, most of the team's time was devoted to travel. When groups were questioned about possible smallpox cases, vaccination was offered but no attempt was made to persuade those unwilling to be vaccinated or to vaccinate all persons in an area except where there was an outbreak. Outbreak containment consisted only in vaccinating those in geographical proximity. With so few staff, it was impossible for the team to remain at an outbreak site to ensure the isolation of the patient or the vaccination of absent contacts or of visitors who later came to the village. Not surprisingly, some outbreaks persisted for many weeks after the team's departure, and some resulted in the spread of smallpox to other villages.

During the first 6 months of 1973, an average of only 590 cases was discovered each month; 115 *woredas* reported cases—64 fewer than during the same period of 1972. With fewer cases and fewer outbreaks, surveillance staff were able to devote more time to search, and additional manpower could be concentrated in problem areas. From April to September the number of cases decreased steadily, reaching a low of only 71 cases in September. Areas known to be infected were few in number and widely scattered except in the central zone (Fig. 21.6).

In preparation for what was hoped might be the last smallpox season, an international seminar was convened in Addis Abeba at the end of the rainy period to which were invited representatives from the French Territory of the Afars and the Issas, Kenya and the Sudan. All these countries by this time were smallpox-free, the Sudan having been the last to eliminate the disease (at the end of 1972). Plans were coordinated for continuing surveillance along border areas and the possibility was explored for teams from these countries to undertake surveillance

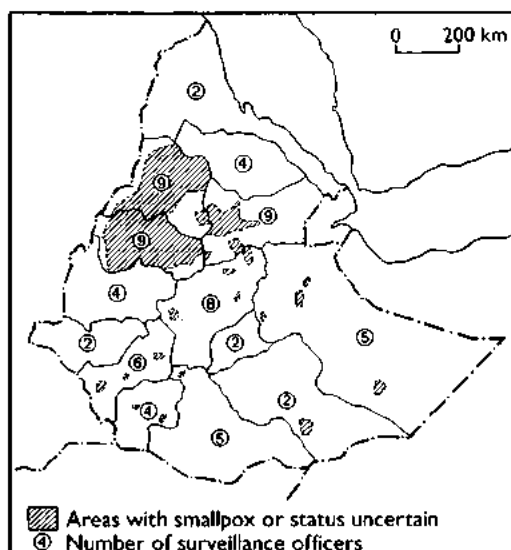

Fig. 21.6. Ethiopia: areas with endemic smallpox and number of surveillance agents assigned to each province, as of 30 September 1973.

programmes within Ethiopia in areas adjacent to their borders.

The remaining endemic areas, principally in Gojam, Gonder and Welo, were comparatively small but they posed enormous problems. The population was predominantly Amhara, many of whom adamantly refused vaccination despite the persuasive efforts of government leaders, village chiefs and priests. Meanwhile, variolation continued to be widely practised, performed by the heads of households when cases occurred in the vicinity. The terrain was the most mountainous and rugged in all of Africa and throughout much of the area security was a problem. In some areas, there was no government presence and smallpox eradication staff were forbidden to enter. It was apparent that helicopters would be invaluable for surveillance, but they were costly; appeals at this time to donor agencies as well as to the Ethiopian army met with no response.

To persuade villagers to accept vaccination sometimes required the teams to remain in an area for extended periods. The overcoming of resistance to vaccination required a somewhat different approach in each village. Some people accepted vaccination only if it was performed on the wrist (the site normally used for variolation); some would accept it only if it was administered by jet injector; in other areas, additional medications had to be

provided first. Not infrequently, weeks of inducement and cajoling were required to vaccinate even half the population of an infected village. Ethiopian and WHO staff showed unusual stamina, courage, imagination and persistence in solving the formidable array of problems, especially notable leadership being provided by 3 Ethiopian health officers—Ato Bono Hora, Ato Wassihun Woldetensie and Ato Zein Ahmed. Time and manpower were required, however, both of which were in short supply. Because of the special problems in these provinces, 2 additional WHO epidemiologists were recruited to permit the assignment of one to each of the 3 provinces, leaving 2 advisers to work with Ethiopian coordinators throughout the remaining 11.

In the autumn of 1973, an unforeseen disaster occurred. The eastern and north-eastern parts of Ethiopia experienced an extremely severe drought, followed by famine, during which an estimated 200 000 persons died. This was accompanied by an unprecedented migration of nomads into the highland areas and by a large-scale migration of the population from the endemic areas of Welo Province into other provinces. Many cases were imported into smallpox-free areas and into the neighbouring country of Somalia and the French Territory of the Afars and the Issas.

Because of the extensive movement of refugees, the number of cases increased to 542 in November and 508 in December, almost as many as had occurred during these same months in 1972. For the year as a whole, however, the 5414 recorded cases represented a decrease of nearly 70% from the 1972 figure of 16 999 cases. Ninety percent of the cases were from only 5 provinces, in which half the smallpox staff were concentrated. During 1973, 2 additional provinces, Gamo Gofa and Arsi, succeeded in interrupting transmission, bringing the number of smallpox-free provinces to 6. Much had been achieved, but it was becoming apparent that the eradication of smallpox from Gonder, Welo and especially Gojam was anything but a certainty. Resistance to vaccination in these areas was reflected by the proportion of the population that had been vaccinated. By the end of 1973, 8.3 million people in Ethiopia as a whole had been vaccinated, a total equivalent to one-third of the population, but in the central zone provinces, the corresponding proportion was only 20%.

### A Year of Turmoil, 1974

The optimism and high expectations of early 1973 that a rapid interruption of transmission might be achieved had given way to the recognition that an arduous task lay ahead which would require the utmost persistence and imagination. Greater support from the government and the involvement of more Ethiopian staff were essential in order to cope effectively with uncooperative populations. Increased financial support from international sources was also required but was difficult to obtain. At this time, WHO considered the eradication of the severe variola major in Asia to be of higher priority, and such discretionary funds as were made available to the Organization had to be directed to the programmes in Bangladesh and India. Possible bilateral support for Ethiopia, meanwhile, remained in suspense as increasing civil strife began to envelop a country beset with economic crises, famine and rebellion against the traditional feudal system of government.

The programme's resources were primarily concentrated in the central zone provinces but the working conditions there became increasingly difficult. Because of armed conflict, *woredas* and sometimes entire *awrajas* were declared by the army to be too dangerous to permit work to continue. In other areas, the teams had to travel with a security escort. In Welo and the south-east, in which outbreaks accompanied refugees, the teams sought and obtained assistance in reporting and vaccination from relief workers distributing food supplies.

Special assistance to the programme was provided during the early months of 1974 by health staff from the French Territory of the Afars and the Issas, Kenya and the Sudan in an exceptional display of international cooperation. It was beyond Ethiopia's capacity to contend successfully with the outbreaks among nomads and refugees in the huge eastern desert areas. Here, with the full approval of Ethiopia, the authorities of the French Territory of the Afars and the Issas responded by providing 5 teams, comprising 46 persons supported by 20 vehicles and 3 helicopters for a 6-week programme of search and vaccination. This operation extended up to 300 kilometres inside the Ethiopian border in the eastern part of Welo and Hararge. To support the effort, Ethiopian staff established petrol depots at key points and accompanied

### The Sudanese Search in Western Gojam Province

Search and vaccination in the difficult area of western Gojam Province were undertaken by a Sudanese team in a journey characterized by great ingenuity and determination. Travelling in 3 Land Rovers, 12 persons required 2 months to traverse some 250 kilometres through Gojam Province from the Sudanese border to the town of Bahir Dar in Ethiopia. Led by a Sudanese sanitarian, Mr Abdul Gadir El Sid, the team had to carry with it all the petrol and most of the supplies needed. Sudanese pounds were acceptable currency for the purchase of food over half the distance; for the last part of the journey, the team members needed Ethiopian dollars, and to obtain them they sold a supply of blankets which they had brought with them just for this purpose. The "roads" over which they travelled had not been traversed for years. It was necessary for them to construct bridges and in many areas to walk ahead of the vehicles, clearing a path with large knives. In some places, the underbrush was so dense that it had to be burnt (on one occasion the flames nearly consumed one of the vehicles). Mechanical breakdowns, poisonous snakes, wild animals and insects were daily problems. Nevertheless, they persisted in their journey, during which they contacted and vaccinated some 20 000 people but found no smallpox. They were gratefully received in Bahir Dar by Ethiopian staff, provided with Ethiopian dollars and, after a brief rest, returned home by the same route.

the French teams, coordinating the overall work through the transceiver network. Meanwhile, a Sudanese team of 12 persons with 3 vehicles undertook a 2-month programme of search and vaccination throughout the western third of the difficult Gojam Province. In the south, Kenyan teams began a continuing programme of search and vaccination in Ethiopian *awrajas* adjacent to Kenya.

Every possible effort was being made to augment the capacity of the programme through cooperative work with the regular health services staff, relief workers and others. Even the malaria eradication staff began to participate after several cases of smallpox had occurred among the malaria workers themselves. The coordination of such disparate groups and activities was difficult, however; it became even more so when, because of the intensifying civil war, a number of foreign volunteers left the programme. Ethiopian health officers and sanitarians served to fill the gap, their efforts being augmented by students who were hired as temporary staff during an extended holiday from the university, which was closed owing to the civil unrest.

Despite the chaos and obstacles, progress continued to be made. Transmission was interrupted in April in Kefa Province, leaving the entire south-west zone smallpox-free. In the northern zone provinces of Eritrea and Tigray, only one importation occurred and this was contained. In the south-east

zone, the outbreaks were contained in the populous areas of northern Hararge by mid-year. Smallpox continued to spread among desert nomads, but few of the staff believed that transmission could be long sustained in this sparsely settled area. Gonder, Gojam and Welo remained the principal areas of concern.

More resources were required for the central zone provinces and, in June, came the welcome announcement that the Surgeon General of the United States Public Health Service had arranged to make available US\$220 000 from his domestic health budget allocation specifically for the lease of 2 helicopters. Planning began immediately to mount a special search programme, to commence in late 1974, as soon as the helicopters, pilots and mechanics had arrived. A Canadian company, under contract to WHO, arranged to fly the helicopters to Ethiopia and recruited Canadian pilots and mechanics, under the leadership of Mr Robert Lavack and Mr William Waugh. Meanwhile, it was decided to make intensive efforts to continue the programme throughout the rural areas despite the difficulties of travel created by the advent of the rainy season.

The challenge of keeping the programme in operation was already enormous, but in 1974 the situation was exacerbated by the beginning of a major revolution. The Emperor was deposed and a new government with a different administrative structure began to take shape. An important tenet of the

### The Death of Dr Petrus Aswin Koswara

The emotional and physical strain associated with field work in Ethiopia was especially great in 1974; it cost the life of one WHO smallpox eradication programme adviser, Dr Petrus Aswin Koswara. He was the only WHO adviser to die while actively engaged in the programme. After serving brilliantly as the director of the successful programme in Indonesia, Dr Koswara joined the Ethiopian programme in 1972. In 1974, he was working in Welo Province, where he was responsible for the planning and logistics associated with the new helicopter-assisted search programme. On returning from Welo one afternoon after weeks of exhausting strenuous field work, he experienced severe chest pain and died that night of a heart attack. He was only 43 years old. His wife and their two children returned to Jakarta, where Dr Koswara was buried. He was decorated posthumously by the President of Indonesia and given a state funeral.

new government was the abolition of the feudal system of land tenure, an action welcomed in most areas but forcefully resisted in others. At the same time, the long-standing revolt in Eritrea intensified; violence increased among the Amharic peoples of the central zone; and the traditional antagonisms between Ethiopians and ethnic Somalis throughout the Ethiopian portion of the Ogaden desert erupted into sporadic open warfare as armaments began to be supplied to guerrilla forces calling themselves the Western Somalia Liberation Front. These problems persisted over the succeeding years, never completely subsiding. Some of those engaged in hostilities were supportive of the smallpox eradication programme and arranged for the staff to work in areas otherwise inaccessible to government authorities. Others, however, attacked smallpox eradication teams, kidnapped some of them, and on one occasion killed 2 of the Ethiopian vaccinators. Nevertheless, programme staff continued their work, both Ethiopian and international workers often serving in areas in which no other government staff could operate.

The special campaign employing helicopters began, as planned, in mid-November 1974 with the object of searching the more inaccessible highland areas. This took careful preparation as fuel depots had to be established and a scheduled programme of search elaborated for areas of which existing maps, at best, only approximately represented the actual terrain. Camping equipment and food were also necessary because supplies in the drought-stricken areas were scarce. The helicopters, operating from base camps, ferried teams into the most difficult and remote areas.

**Plate 21.8.** P. A. Koswara (1931–1974) seated (centre) with 2 Ethiopian colleagues, Endale Alemayehu and Tedla Tegegn, shortly before his death.

Thereafter, the teams proceeded by foot and on mules to an arranged pick-up point over a period of 7–10 days. The helicopters provided logistic support and were used to transport staff to confirm rumours of outbreaks. The teams searched for cases and performed vaccinations. Where resistance to vaccination was encountered, administrative officials were flown in to help to persuade the villagers. As these operations progressed, the staff were surprised to find that, in many areas, resistance to vaccination was less of a problem than it had been before. This phenomenon was attributed in part to the dramatic appearance of teams by helicopter.

BY COURTESY OF D. A. HENDERSON

**Plate 21.9. A:** Helicopters were used in the Ethiopian programme from 1974 for smallpox searches in inaccessible areas. Although they could carry 4 passengers at sea level, they could not transport more than 3 persons at the high altitudes of the vast central mountainous area. **B:** The limited flight range made it necessary to establish depots of fuel drums in camps.

The helicopters greatly facilitated efforts but an operation such as this was costly and was attended by other problems. One hour of flying cost about US\$250 and thus careful planning of use was mandatory. Moreover, the 4-passenger helicopters did not have a great range and at the high altitudes of the central plateau could not transport heavy loads. Thus, fuel depots had to be carefully sited and accessible by the heavy trucks required to transport the drums of fuel from Addis Abeba. Serious delays in the schedule occurred when helicopters experienced mechanical failures or other events took place.

Such incidents included the destruction of one helicopter by a hand grenade shortly after a team's arrival in a village; a second was hit by a bullet which penetrated the fuel line, causing a fire and a forced landing. On another occasion, a helicopter lost its bearings, made a forced landing when fuel ran out, and was not found for 2 days. And on yet another occasion some years later, rebel forces captured a helicopter and pilot and held them to ransom (Plate 21.10). Although nobody was injured or killed as a result of these incidents, some of the pilots returned home within days of arriving in Ethiopia. Most

**Plate 21.10.** William Waugh, a Canadian helicopter pilot, was captured in 1977. He managed to send this message to Ehsan Shafa, of the Smallpox Eradication unit at WHO Headquarters, who was in Ethiopia. It reads: "April 7-77 Dr. Shafa We are captured by the Guerillas they want \$40 000.00 Ethiopian dollars for my release or they will kill us, Bill Waugh". He was released 4 days later when this picture was taken, without the ransom having been paid.

were undaunted and became as expert in the diagnosis of smallpox and the strategy of the programme as the senior programme staff.

The helicopter-supported operation detected fewer smallpox outbreaks than had been expected; most of those discovered were rapidly contained. In Gonder, few cases were found and by December the persistent focus in one *awraja*, which was responsible for 60% of cases in the area, had been eliminated, leaving only one seriously affected *awraja*. In Welo, fewer smallpox cases were discovered in the northern area than had been expected, although continuing transmission in the south remained a problem. In Gojam, by the end of the year, smallpox appeared to be limited to only 24 of the province's 1800 *debers*.

By the end of 1974, 4439 cases had been discovered, 20% fewer than during the previous year; the number of provinces in which transmission had been interrupted had risen from 6 to 8 as both Kefa and Sidamo in south-western Ethiopia became smallpox-free. Search continued in both of these provinces but the few cases that were found could be identified as importations and were quickly contained.

#### The Final Phase, 1975-1976

At the beginning of 1975, with mounting civil disorder and with increasingly large

areas in the endemic provinces inaccessible to the programme staff for long periods of time, it seemed more and more questionable whether adequate resources could be deployed sufficiently quickly and effectively to interrupt transmission. In fact, it seemed possible that the degree of control that had been achieved was at risk of being lost, which would permit smallpox to spread widely through Ethiopia and into other countries. If additional resources were to be made available, however, they would have to be drawn from other programmes. But eradication of the severe variola major in Asia continued to have priority, and although excellent progress was being made in India and Nepal, in the early months of 1975 Bangladesh experienced major epidemics (see Chapter 16) associated with famine and extensive movements of refugees. Not until the summer of 1975 was it reasonably certain that smallpox could be eliminated from Asia. When smallpox transmission was interrupted in India in May 1975 and in Bangladesh a few months later, it was possible to divert resources and energies to Ethiopia—then the world's last remaining country with smallpox. At this favourable turn of events, Ethiopian and international staff alike renewed their endeavours to attain what had once seemed such a distant target—"Smallpox Zero".

### Surveillance of Smallpox in a Hostile Area

A special problem faced by the smallpox eradication staff was surveillance among a population living in the Blue Nile gorge, a ravine which formed the southern border of Gojam and was one of the widest and deepest in the world. At least 2 days were required to travel from one edge of the gorge to the other. Large numbers of people inhabiting the gorge were hostile to the intrusion of strangers; when the teams visited, they often had to be accompanied by armed security forces. During much of 1974–1975, the teams were unable to enter the gorge at all and thus were limited to conducting surveillance–vaccination activities around its rim. On one occasion, rumours were received about the existence of smallpox in one of the villages, whose inhabitants were thought to have been responsible for killing the members of a German Blue Nile expedition. A young schoolboy who was a native of the area and had relatives in the village volunteered to investigate. He went to the village and, while playing with other children, succeeded in obtaining scabs from a child who had experienced a disease with rash. Laboratory investigation confirmed it to be smallpox.

It was not until 1977 that the fighting subsided sufficiently to permit search teams, accompanied by civil guards, to travel widely through this area. Fortunately, transmission had ceased by then even though few persons had been vaccinated.

Throughout the summer of 1975, the staff, still numbering less than 100, continued the struggle with smallpox in the highlands of the central zone and adjacent areas of Shewa, as well as in the Ogaden desert area of Hararge (Fig. 21.7). Unexpectedly, additional manpower became available when the authorities decided to send 60 000 students into villages throughout the country in a special campaign to improve literacy. The government agreed that some could also work with the smallpox eradication teams, and thus many were trained in techniques of case search and vaccination. The students proved to be especially valuable, since they were natives of the area in which they were working and could both identify persons with political

influence and induce the villagers to accept vaccination.

Progress in Asia eventually came to be measured in terms of the number of currently “active outbreaks” in a village or sector of a town—i.e., those in which a case had occurred during the preceding 6 weeks. This system of measurement was introduced into the Ethiopian programme in 1975 but it was difficult to apply. An epidemiologist was required to revisit the site of an outbreak after 6 weeks to confirm that transmission had ceased and that the site could be removed from the list of “active outbreaks”. Because of the paucity of staff and the periodic prohibitions on travel in large areas, such visits were sometimes unavoidably delayed. Moreover, it

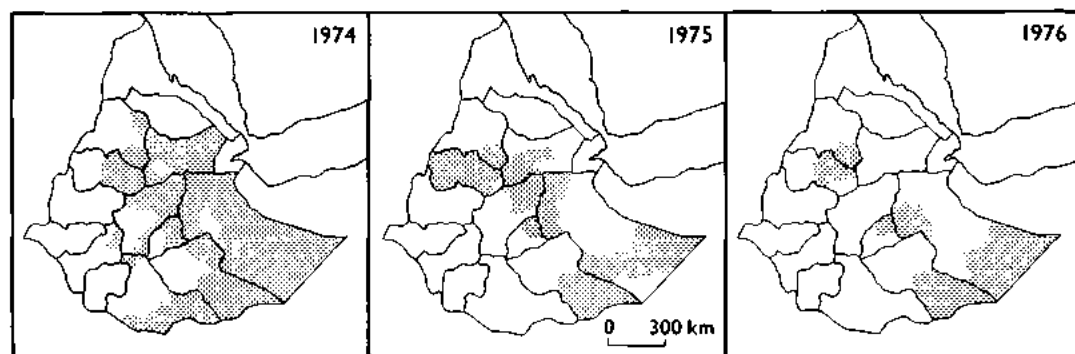

Fig. 21.7. Ethiopia: Awraja areas (shaded) in which cases of smallpox were reported, 1974–1976.

was no easy matter to deal with an Ethiopian "village", a collection of houses often dispersed over many square kilometres. Nevertheless, the staff began to define the smallpox problem in this way and by mid-year had evolved a reasonably effective data collection system. By the end of July 1975, there were only 131 known active outbreaks occurring in 13 clusters. The clusters were spread over about 15 360 square kilometres, little more than 1% of the country's total area (Table 21.10). Many of the outbreaks in Gojam, Shewa and Gonder, however, had occurred in areas which the teams had been forced to leave because of civil strife, thus precluding their removal from the list of active outbreaks.

As civil disorder was so widespread, some embassies decided that effective work in the countryside was impossible and too dangerous and so terminated the assistance of their countries; the remaining volunteers from Austria and the USA were withdrawn, although those from Japan continued to work. The smallpox eradication staff, however, believed that they might yet be successful if conditions did not deteriorate further. In fact, the problems became more acute. Petrol for vehicles, which had been in short supply, was brought to the capital by truck in an armed convoy from the coast. In June, because of the destruction of a major road bridge, the supply line was interrupted and rationing was imposed in Addis Abeba. In many parts of the country, no petrol at all was available. However, the Acting Resident Representative of the United Nations Development Programme, Mr John Phillips, who in 1971-1972 had been instrumental in initiating the smallpox programme in Botswana (see Chapter 20), worked out an imaginative scheme with the French government and an oil company to ship petrol by train from the city of Djibouti to Addis Abeba.

From there it was distributed to the regions by truck and by a chartered DC-3 fixed-wing aircraft. Fortunately, there remained a large residual stockpile of aviation fuel in Addis Abeba which the government made available to the programme, thus permitting continued helicopter operations.

In July 1975, Henderson held meetings with Ethiopian and WHO staff to plan an intensified programme extending to the end of 1976. It was hoped to utilize monetary contributions from Canada, the Netherlands and the USA, vaccine from the USSR and additional support from the WHO regular budget. The revolutionary government agreed to issue a proclamation declaring the programme to be of the highest priority. The new plan provided for 85 Ethiopian surveillance officers, 16 WHO advisers and as many as 1200 temporary field staff; the number of helicopters was increased from 2 to 4; additional vehicles and considerable quantities of camping equipment were also provided.

In October, more ample facilities were made available for the programme's headquarters, including an automotive repair shop. At the end of the year, an exceptionally able Ethiopian health officer, Ato Yemane Tekeste, was named director of the programme; Dr Weithaler continued to serve as its senior WHO adviser.

Activities steadily intensified, especially in the highland plateau areas, to which the most able Ethiopian and WHO staff were assigned. With additional locally recruited staff available, it became possible to assign teams to search for cases more widely and more frequently and to remain in outbreak areas until transmission had ceased. However, areas in which organized operations could not be undertaken because of the lack of security continued to be a problem. In many of these areas, locally recruited staff who were known to the dissidents opposing the government were sometimes able to travel quite extensively to search for cases and to vaccinate, although not without risk. It was during this period, in Gojam, that one worker was killed and a second captured and presumably killed by dissident groups.

By the end of 1975, smallpox transmission had been interrupted in 2 more regions, Shewa and Welo. No cases were detected in Gonder between July and December 1975, but because of the extent of the areas that could not be searched, the staff remained

Table 21.10. Ethiopia: status of smallpox as at 23 July 1975

Regions	Number of clusters	Number of active outbreaks	Approximate area (km <sup>2</sup> )
Hararge	3	6	2 517
Shewa	1	24	3 600
Welo	2	6	234
Gonder	2	15	2 450
Gojam	4	79	6 550
Bale	1	1	9
Total	13	131	15 360

uncertain as to the true situation in the province. The main problem was presented by Gojam, in which 4 contiguous *woredas* in and adjacent to the Blue Nile gorge, all heavily infected, could not be entered, and from this source cases were repeatedly exported to other areas. The teams sought to contain this focus through the surveillance and vaccination of the population of adjoining areas, but many individuals resisted vaccination.

The other principal focus of smallpox was in the vast Ogaden desert. Smallpox among the nomads had spread slowly but steadily from the highlands of the north-west into the Ogaden desert area of south-eastern Hararge, with occasional spread into Bale and Arsi Regions. From the initial reports of smallpox eradication staff in the area, there appeared to be few problems in containing this focus. They guessed that the affected population was not more than 300 000, of whom a third lived along a river, readily accessible by vehicle. As a result of the vaccination of people settled along the river, of refugees receiving food at shelters, of nomads when they stopped at water-holes and of other individuals contacted during search operations, the WHO epidemiologist estimated that at least 60% of the population had been protected. In a population so sparse and scattered, and so well vaccinated as this, everyone agreed that continuing transmission should cease quickly. However, the possible spread of smallpox into the part of the Ogaden desert that lay within Somalia was also a source of concern. Accordingly, periodic border meetings were arranged between Ethiopian and Somali staff. The Somali programme director reported at one of these border meetings in August 1975 that 85% of the nomads in Somalia had been vaccinated and assured everyone that surveillance in Somalia was most thorough. Only much later did it become evident that both Somali and Ethiopian staff assigned to the Ogaden area had greatly overestimated their achievements and underestimated the size of the population and the severity of the problem.

The early months of 1976 were characterized by far more intensive efforts but increasing organizational turmoil. The arrival of additional WHO epidemiologists and the acquisition of more vehicles, 2 more helicopters and a small fixed-wing aircraft, as well as the employment of many more local staff, overtaxed the capacity of the administrative structure. The helicopters began to be sched-

uled for as many as 8-10 flying hours a day, which exceeded safety limits and created difficulties in providing the requisite maintenance. Close field supervision of the increased staff became more difficult; the provision of field supplies was increasingly delayed; and the effective management of funds for the field payment of temporary staff and the purchase of supplies deteriorated. On a field visit in late February 1976, Henderson found a well-organized operation in progress throughout Gojam, Welo and Gonder under the overall supervision of Dr de Quadros and directed at regional level, respectively, by Ato Bono Hora and the WHO epidemiologists, Dr P. R. Arbani from Indonesia and Mr Gary Urquhart from the USA. In other areas the situation was less satisfactory. In northern Hararge, Henderson discovered that 5 outbreaks of chickenpox had been misdiagnosed as smallpox by inexperienced field staff. The most disturbing observations were made in the Ogaden, where supervision and organization were seriously deficient. At a watering-place only 20 kilometres from the Somali border, a smallpox isolation hut, located in the middle of a nomad camp, had no watchguard and was frequently visited by people from the camp; many unvaccinated persons were found in the area. At another camp, 2 individuals were encountered who had been

**Plate 21.11.** Poerwokoesoemo R. Arbani (b. 1941) was a WHO epidemiologist in Ethiopia, 1975-1979, having previously served in the same capacity in Pakistan since 1973. Before that, he had played an active role in the eradication of smallpox from Indonesia.

infected in the office of the camp physician by patients summoned for examination from the smallpox isolation facility. It was apparent that the optimism of the field staff in the Ogaden was unfounded.

The management of the programme was reorganized on 5 March 1976, and from then on rapid progress was made. A special task force for the endemic regions was created, with Ato Yemane Tekeste as programme director, Dr de Quadros as chairman, Mr Lavack as director of helicopter support operations, and Mr John Copland, administrative officer for smallpox at WHO Headquarters, as finance officer. Dr Weithaler was assigned to coordinate activities in the non-endemic areas; Ato Tesfaye Temelso and the WHO epidemiologist Dr Bert van Ramshorst assumed responsibility, under the direction of the task force, for operations in the Ogaden.

The tempo of activities increased in 1976 as both government authorities and WHO staff sought desperately to contain the world's only remaining focus of smallpox. It was possible to employ additional local staff through the use of funds made available by a special contribution from the USA of US\$3 million in May of that year. New outbreaks continued to occur, however, until August (Fig. 21.8). The focus in Gojam was eventually contained by using armed civil guards who accompanied

teams moving through the area; the last case occurred at the end of March. In Gonder, however, in January, after nearly 6 months without any cases having been detected, search teams were able to penetrate an *awraja* in the Blue Nile gorge which had been inaccessible for nearly a year, but in which fighting had recently diminished. There the teams discovered that smallpox had continued to spread (Table 21.11). Although this focus was near the outbreak area in Gojam, the two were unrelated. An intensive surveillance-containment programme was conducted, again employing civil guards, but transmission was stopped only with difficulty. As the search was extended around this area, another focus of 24 outbreaks with 140 cases was discovered 120 kilometres to the north. An itinerant musician had introduced the disease in December 1975 from the Blue Nile gorge. Fortunately, the population in the infected area proved to be receptive to vaccination, and on 29 June the last outbreak in the central zone provinces was discovered and contained.

Meanwhile in the Ogaden desert areas of Hararge and Balc, smallpox outbreaks continued to occur among the nomads, but the sources could rarely be traced because of the frequent movements of the different nomadic bands. Additional resources were deployed there in March and a better organized, more systematic pattern of search was developed employing more than 200 locally recruited staff.

In addition to helicopters, fixed-wing aircraft were chartered by WHO, and others were provided by the Netherlands and the Norwegian Save the Children Foundation. Search activities were compromised by sporadic fighting and the occasional kidnapping of staff and WHO advisers, who were taken to Somalia but eventually released through the intervention of United Nations officials. In addition, during this period 9 of the programme's vehicles were seized and taken across the border. The Somali guerrilla forces sometimes hampered operations, but more often than not took steps to protect the teams. In one town, to which a team had been brought by helicopter, notice was given by guerrilla forces that an attack had been planned and that the team should leave. As the helicopter took off, fighting immediately broke out. On other occasions, guerrilla forces attacked government buildings, killing the occupants, but did not molest the personnel of

smallpox camps in the same town. For Ethiopian and WHO staff alike, working in the Ogaden was a trying experience. Many participated in the operation but special credit must go to the dedicated Ethiopian staff, to the helicopter pilots, and to Ato Tesfaye Temelso, Dr van Ramshorst (Netherlands), Dr do Amaral (Brazil), Dr M. N. El Naggar (Egypt), Dr Alexander Gromyko (USSR), Mr Carl Hasselblad (USA) and Dr J.-P. Ryst (France).

Gradually, it became apparent that in the Ogaden desert, smallpox was persisting primarily as a result of transmission back and forth between desert nomads and agri-

culturalists settled along the Shebele river, which divided Hararge and Bale. Efforts to control the spread, however, were severely hampered in the summer by the most serious flood in decades, which destroyed roads and river crossings and displaced numerous villagers. Across the river in the southern half of Bale, fighting between Ethiopian and guerrilla forces had greatly intensified and not until the middle of July was it possible for teams to enter this area. On 22 July, one of the teams discovered an outbreak in the small nomad village of Dimo in Bale, the first case having occurred on 5 June. Containment vaccination was immediately

### A Missing Team—Chronology of Events

Work in the Ogaden was difficult enough. Guerrilla forces made it even more problematic.

#### Events as experienced by Ethiopian staff:

##### 4 June 1977

Early morning—Surveillance Officer Ato Metiku reported to Addis Abeba by radio from Warder (a town in the Ogaden) that the WHO epidemiologist Dr Claudio do Amaral and a team comprising an assistant surveillance officer, 2 interpreters and a driver had not returned as expected on the previous evening. They had gone by Land Rover some 120 kilometres away to check on a rumoured smallpox case.

07.00 hours—The helicopter with Ato Metiku searched without success and returned to base.

10.00 hours—A fixed-wing aircraft joined in a second unsuccessful search.

15.00 hours—The two planes began a third search and at 17.50 hours, the vehicle was sighted. Because dusk had fallen it was decided to send the helicopter the following morning.

##### 5 June 1977

06.00 hours—The helicopter flew to the site and many people were seen gathered around the vehicle waving white cloths. Fearing gunfire, the helicopter had to remain at a distance. From there, no team members could be identified.

12.00 hours—The helicopter returned to the site; this time a truck was observed parked next to the vehicle, again with many people surrounding it but no one waving.

15.00 hours—Two locally recruited Ethiopian staff volunteered to be dropped near the site (about 3 kilometres away) to obtain information. Special signals were arranged for them to identify themselves to the helicopter, which would keep watch from a distance and pick them up on 6 June at a site 30 kilometres away, on signal.

16.00 hours—The helicopter returned to the site but the vehicle was gone and the volunteers could not be seen. On returning to base, the truck seen previously was spotted. As the helicopter flew closer 2 individuals jumped from the truck and began firing at it.

Evening—At a special meeting, it was decided to bring in a second helicopter for search; 2 additional Ethiopian staff volunteered to be dropped at the site on the following morning hoping to learn something of the fate of their colleagues and of the team.

##### 6 June 1977

07.30 hours—The volunteers were dropped at the site; helicopter search continued over a widening area.

14.00 hours—A flight over the original area revealed no sign of the volunteers.

16.00 hours—The helicopters flew to the pick-up site; one volunteer was seen but did not signal. The pilot returned to base at 19.15 hours.

Evening—Ato Metiku arranged in secret with the town-dwellers' association for a group of villagers to walk to the site.

##### 7 June 1977

It was decided that all the aircraft should undertake a final area-wide search and then await instructions. Arrangements were made for a DC-3 fixed-wing aircraft to fly additional fuel to the area. The volunteers were located and retrieved by the helicopter; they had been unable to obtain any information.

##### 8 June 1977

The Director-General of WHO sent a telex from Geneva to the Minister of Health of Somalia requesting assistance from the Somali border guards. Daily telex and telephone contact was established by Geneva with Addis Abeba and Mogadishu.

*9 June 1977*

A surveillance officer from Warder reported that a villager had told him that he had seen Dr do Amaral and the team on 6 June being taken by guerrilla forces to Deghbur, another area in the Ogaden.

Ato Yemane Tekeste and another high-ranking Ethiopian official left for Deghbur to be available to participate in negotiations should the captors make contact with the government.

*11 June 1977*

A telex was received in Geneva from the WHO Representative in Mogadishu with the message that the team was in Hargeisa, Somalia.

**Events as related by Dr Claudio do Amaral:**

*3 June 1977*

We left Warder at 07.00 hours to investigate a rumoured smallpox case 120 kilometres to the north. About 80 kilometres from Warder, 2 men with sub-machine-guns started shooting at us and ordered us to stop. Within minutes, they were joined by many others who ordered us out of the car, took everything we had and made us lie on our backs with our arms up. At that moment, I thought it was the last day of my life! Suddenly, one of their leaders appeared and took us to a village 300 metres from where we had been captured. He identified the group as being soldiers of the Western Somalia Liberation Front. We talked about the smallpox eradication programme and what we were doing, but he said that we had no right to be in the area, and emphasized that they could release us or kill us as they chose. We were given Somali dress and provided with goat meat and camel milk. We slept that night in the open air guarded by 2 men with sub-machine-guns.

*4 June 1977*

At about 15.00 or 16.00 hours we heard the helicopter and saw the fixed-wing plane but I hid, fearing they might land and be captured. That night we slept in the same place.

*5 June 1977*

In the morning, we again saw the helicopter and with a gun at my head, I was told to contact the pilot by radio to request him to land. I convinced our captors, however, that radio contact was not possible. The leader then ordered me to take off my shirt so that they would see my white skin and be persuaded to land. Again, I refused, persuading him that the pilot could not recognize colour from such a great distance. Fortunately, neither plane tried to land. Surprisingly, in the late afternoon, a vaccinator appeared who was from the village to which we had intended to go. He reported that the case we had intended to see was chickenpox, not smallpox! We were then driven to another village, where, we were told, we should be informed as to what would be done with us.

*8 June 1977*

After 2 days when nothing appeared to be happening, we were driven to yet another village, 120 kilometres further away, where we met a more senior leader. Once again, I showed my passport, explained I was Brazilian and described the smallpox eradication programme. To my great surprise, he knew all about our movements as well as the names of all the epidemiologists and where they were stationed. The leader said they would hand us over to the Somali authorities. That night they gave us a small hut and blankets for sleeping.

*11 June 1977*

We were handed over to the National Somalia Security authorities and arrangements were made for me to fly to Mogadishu on 18 June and to Addis Abeba on 22 June. The vehicle, after repair, was to be returned to Ethiopia.

instituted. In all, 16 cases occurred, 9 of the persons concerned having been variolated. The Dimo outbreak proved to be the last in Ethiopia, (Table 21.11) and for many weeks it was thought to have harboured the world's last case of smallpox—that of a 3-year-old girl who had become ill on 9 August. She had been variolated as well as vaccinated during the incubation period of the disease.

Active search continued and intensified throughout the country, on the assumption that in a country so large and with so many inaccessible areas, smallpox must be present somewhere. In many areas, especially in the south, the task of search was greatly facilitated by the new farmers' cooperatives and urban dwellers' associations. Through contact with the leaders of such organizations, it was possible to explain the objectives of the programme and to enlist the assistance of the population in reporting suspected cases. To encourage such reports, a reward was offered, a practice first initiated in January 1975 in Gonder.

Surprisingly, week after week passed with no additional smallpox foci found anywhere in Ethiopia. Except for the cases found in late July and early August in the nomad village at Dimo, none occurred in the Ogaden with an onset of illness after July; in the highlands the last case had occurred on 5 July. Search teams, posted in each *awraja*, were able to intensify their efforts in September and October as the seasonal rains ended, but still no cases were found.

Plans were made to hold a press conference at the end of October 1976 in the expectation that an announcement could be made that 10 weeks had elapsed since the onset of what was believed to be the world's last case of smallpox. Confirmation of eradication would require 2 full years of search, but week by week it appeared increasingly certain that no further cases would be discovered. Television crews flew to Dimo to take pictures of the village and of the last known patient, Amina Salat.

In late September plans were abruptly changed when cases of smallpox were reported from Mogadishu, the capital of Somalia. Initial disappointment that a few last imported cases had necessitated delay of the announcement turned to despair as it gradually became apparent that Somalia had endemic smallpox. Despite assurances to the contrary, neither surveillance nor vaccination activities had been well conducted. It had been anticipated that the last chapter of the global eradication of smallpox would be written in Ethiopia—but it was not to be.

### Morbidity and Mortality Data

From the time the programme began, data collected from all households in which cases occurred included the name, age and sex of all residents and their past experience with regard to smallpox, vaccination and variolation. Data from Ethiopia are, in fact, more

MARION KAPLAN, 1976

complete than those from any other country which experienced extensive endemic smallpox. Information on the age and outcome of illness are available for 54 991 of the 58 031 cases reported from 1971 to 1976 (Table 21.12). One-fourth of all cases (26%) occurred among persons aged 15 years and over who comprised 57% of the population. The large proportion of cases among adults is characteristic of an area in which the presence of smallpox was infrequent among much of the population. The proportion of cases among those less than 1 year of age (2%) is almost certainly understated because, in many areas, very young children with smallpox were often hidden from investigators.

Only variola minor was observed. No outbreaks were discovered with case-fatality rates comparable to those in Asia or western Africa. The overall case-fatality rate was calculated at 1.5%. The true figure may, however, be somewhat higher because outbreaks that occurred in the early years of the programme were not observed throughout their course and the deaths of some patients during the second or third week of illness may have been missed. Nevertheless, it is doubtful that the actual rate was much higher than 2%, a rate characteristic of variola minor.

Cases occurred almost exclusively among the "never vaccinated" group, only 961 of 49 106 persons of known vaccination status having previously been vaccinated. Even some of those listed as "vaccinated" had been vaccinated too late in the incubation period of the disease to be protected. Of the total number of cases, 7.3% occurred among persons who had been variolated.

Secondary attack rates among susceptible individuals within families were comparable to those measured elsewhere. Nearly 80% of children under 15 years of age who were exposed in households contracted the disease. Lower secondary attack rates among adults (43.6%) may reflect diminished levels of exposure, but they may, in part, be understated because of the failure of adults to recall past infection (Table 21.13).

Comparatively few children under 15 years of age were immune because of previous smallpox, which suggests that the disease had not been widely prevalent for a number of years. Among household contacts of cases as a whole, approximately equal numbers were immune as a result of variolation and vaccination. Three times as many had previously experienced smallpox.

Finally, data regarding the source of infection of outbreaks (if known) revealed that the

disease rarely spread over long distances. Of 6957 outbreaks analysed, a source of infection was ascertained for 4565. Of these, the source of 3956 (87%) was from contact in the same *woreda* and of another 362 (8%) in the same *awraja*. Only 1 in 20 originated in another *awraja*.

### Exportation of Cases

Ethiopia, as had been feared, was a source of infection for neighbouring countries. The Sudan, which had been smallpox-free in 1967 (see Chapter 18), was reinfected by cases from Ethiopia in 1967-1968 and the disease subsequently became endemic there. One additional importation occurred in the Sudan in December 1972 but was quickly contained. Kenya experienced 2 imported cases in 1970-1971 with 44 secondary cases; 2 imported cases and 2 further cases in 1973; and 1 imported case with 5 further cases in 1976 (see Chapter 19, Fig. 19.4).

The French Territory of the Afars and the Issas and Somalia were the most subject to importations. The former, in December 1971, recorded an outbreak of 104 cases following an importation; in 1973, 10 separate importations occurred with 4 secondary cases; and in March 1974, 12 cases were reported following 1 or possibly 2 importations. Somalia, from 1962 to 1972, recorded only 2 cases of smallpox (1966); the origin of these was unknown. However, from December 1972 to the end of August 1976, when Ethiopia detected its last case, 42 cases were reported, of which 38 were said to have been importations, the last of these occurring in March 1976, 5 months before Ethiopia interrupted transmission. No further cases were reported from Somalia until October. Those cases were said to have originated in Ethiopia but in fact, as was later discovered, endemic smallpox had by then become re-established in Somalia and the official reports of field investigations, at least during the latter part of 1976, were unreliable.

### CONCLUSIONS

Ethiopia proved to be as formidable a challenge to the Intensified Smallpox Eradication Programme as any country in the world, and at every stage. For nearly 3 years,

the government not only declined to discuss a possible eradication programme, but actively opposed it. The idea of a national programme was eventually accepted, with reluctance, and, when it was launched in 1971—the fifth year of the Intensified Programme—little support was given by the government either in resources or in commitment. For more than 3 years, a staff proportionately smaller in number than in any other endemic country struggled valiantly, but with remarkable success, to contain the disease in one of the most rugged and difficult terrains in the world and among hostile populations to whom vaccination was all but unknown. Escalating civil war and famine further confounded the endeavour. The fact that the disease was of the mild *variola minor* variety increased the difficulty, because the population was not particularly eager to be vaccinated; many who were ill with smallpox were able to travel widely, spreading the disease as they went. Adequate resources could not be made available until late in 1975, but with much of the country then smallpox-free, less than a year elapsed before transmission was interrupted. Subsequently, search activities to certify the absence of smallpox were well supported by the government and resources for the task became available. But less than a year later, in 1977, the Somali-Ethiopian war broke out, rendering inaccessible a large portion of the area in which the last cases had occurred. Only through a surveillance programme conducted from bases in Somalia was it possible to continue activities in the troubled Ogaden desert and to confirm the absence of smallpox.

It is a tribute to a dedicated WHO staff and a small band of extraordinarily capable Ethiopian health officers and sanitarians that programme activities were continued at all during several years in many parts of the country. For many years and in many areas, smallpox eradication was virtually the only health programme in operation in the field, and WHO smallpox staff were almost the only expatriate workers who ventured outside the major cities.

Global smallpox eradication was in jeopardy on numerous occasions and in many countries, but nowhere was the outcome so greatly in doubt, and for so long, as in Ethiopia.

Prospects for the successful interruption of smallpox transmission in Yemen had not originally appeared to be much more encour-

aging than in Ethiopia, and indeed the programme, such as it was, was reasonably well executed only during its first year. Yemen, however, was far smaller in size and population; variola major, rather than variola minor, had predominated but apparently had spontaneously died out before the programme began. In Democratic Yemen, whose population was even smaller than that of Yemen, the WHO-supported programme was better executed, but its achievement primarily consisted in confirming the absence of smallpox.

In retrospect, it would have paid rich dividends strategically if, in Ethiopia, greater attention had been paid to smallpox in the Ogaden desert area at an earlier stage. The most competent staff and the larger proportion of resources were initially assigned to the difficult mountainous plateau areas of the north in the expectation that

smallpox transmission would soon terminate—for the most part spontaneously—among the desert nomads. Until March 1976 the programme in the Ogaden was modest and, as became evident, not well organized. When a fully effective programme did take shape, it was soon discovered that vaccinal immunity was far lower than had been recorded, reporting was poor and containment ineffective. Smallpox continued to spread among nomads, but in August 1976 the last known outbreak was finally contained. This would have marked the end of smallpox if the WHO-supported programme in Somalia had been conducted as well as it was reported to have been. However, uncontained importations into Somalia set the stage for yet one more major programme in a country that had previously been free of smallpox. These events are the subject of the next chapter.

### INTRODUCTION

Unexpectedly, the final episode in the global eradication of smallpox did not take place in one of the countries which had recently been so heavily infected, but in Somalia, whose first endemic cases in 14 years were reported in late September 1976. The reports were received 7 weeks after the last outbreak in Ethiopia, at a time when WHO was preparing to announce that, subject to confirmatory search, the world was free of smallpox. It was a bitterly disappointing setback, coming as it did at the end of a 12-month period that had witnessed the occurrence of the last case of variola major in Asia and the conclusion of a difficult but successful campaign in Ethiopia, then thought to be the world's only remaining endemic country. For Somalia to be identified as the last country with endemic smallpox was an embarrassment to its government. It was especially distressing to Somalia's health services, which for years had been sharply, and sometimes justifiably, critical of the programme con-

ducted in adjacent areas of the Ogaden desert by the Ethiopians.

Since 1969 Somalia had been engaged in a WHO-assisted programme of smallpox vaccination and surveillance which national programme staff believed to be highly successful. As late as August 1975, the national programme director, in a meeting with Ethiopian staff at the border of the two countries, reported that 85% of the population had been successfully vaccinated. Although importations of smallpox had been frequent, most of the cases were said to have been detected within a few days of onset. They had occurred among nomads, who roamed freely across the vast Ogaden desert. Between 1972 and February 1976, 38 imported cases were acknowledged but only 4 secondary cases were said to have occurred. No cases were reported between February and September 1976, although later evidence suggests that it was during these months that endemic smallpox became re-established. In September, Somalia's report of smallpox cases brought the prompt assistance of experienced WHO epi-

demologists. These staff members were handicapped by not being permitted to visit the sites of outbreaks or to travel widely in search of cases, but with their Somali counterparts they struggled to interrupt what seemed to be a few tenuous chains of transmission in Mogadishu, the capital. By January 1977, it appeared that they had succeeded. However, a country-wide search for cases was called for, and in March the government agreed to cooperate fully in making this possible. The search soon revealed that endemic smallpox extended throughout southern Somalia. Major epidemics followed, and in May the government declared an emergency.

An intensive operation was therefore started which brought support from many countries and agencies and assistance from WHO epidemiologists who had worked in other endemic countries. The government gave its full support, and on 26 October 1977, only 141 days after the emergency had been declared, the world's last case of endemic

smallpox occurred. Meanwhile, more than 3000 cases had been recorded.

This chapter deals with events in Somalia and, briefly, with the situation in the adjacent French Territory of the Afars and the Issas, which became the independent state of Djibouti in 1977 (Fig. 22.1). The latter country, with a population (1977) of 240 000, experienced periodic importations of smallpox from Ethiopia but the disease never became endemic. Outbreaks were controlled by containment vaccination; mass campaigns were conducted every 3 years.

For a detailed account of the Somalia programme, the reader is referred to the book *Smallpox Eradication in Somalia* (Ježek et al., 1981), from which much of the information in this chapter is derived.

## BACKGROUND

The Somali people, who were predominantly nomadic and semi-nomadic pastoralists, roamed across the largely open and unmarked borders of the Horn of Africa in areas that included Somalia, parts of Djibouti, Ethiopia and Kenya. In 1960, when the country became independent, Somalia comprised the former British Somaliland Protectorate and the United Nations Trust Territory of Somalia, once an Italian colony. Thus, English was widely understood in the north and Italian in the south. Following a military coup in 1969, the country was administered by a Supreme Revolutionary Council and renamed the Somali Democratic Republic. The Somali Revolutionary Socialist Party was founded in July 1976 and provided political and administrative leadership throughout the country's 16 regions and 83 districts. The government's idea of uniting all the Somali peoples in one nation, regardless of existing political boundaries, was a source of contention with neighbouring countries throughout the course of the Intensified Smallpox Eradication Programme. This controversy was manifested in the continuing tension between Somalia and Ethiopia and in guerrilla warfare in areas of Ethiopia adjacent to Somalia in which Somali nomads lived.

### Population Movements and Health Facilities

Nomadic pastoralists, who constituted about half Somalia's population (3.1 million

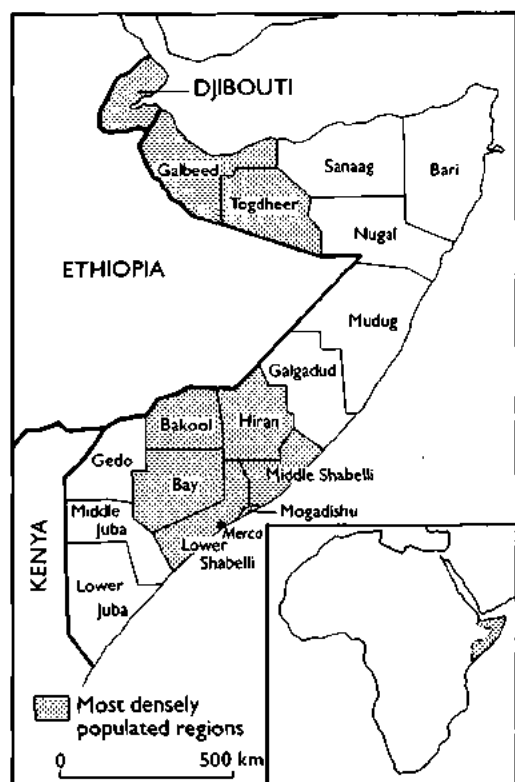

Fig. 22.1. Somalia: Regions and adjacent countries. Before attaining independence in 1977, Djibouti had been the French Territory of the Afars and the Issas.

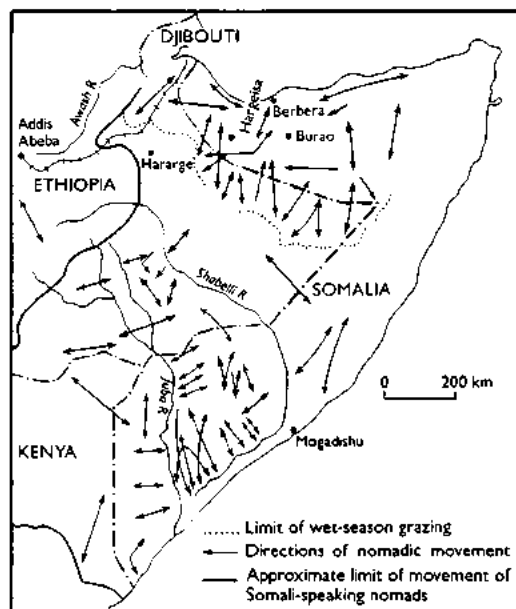

Fig. 22.2. Horn of Africa: approximate area covered by movements of Somali-speaking nomadic pastoralists.

persons in 1975), played an important role in sustaining smallpox transmission, carrying it from one area to another, where it spread among settled populations. An indication of the extent of pastoralism is provided by estimates (1975) of the numbers of live-

stock -3.5 million camels, 15 million goats and sheep, and 4.5 million head of cattle. A large proportion of the settled population was located along the coast in some 60 towns and cities, which were designated as municipal centres. Fewer than 25 of these, however, had more than 5000 inhabitants; by far the largest was Mogadishu (population, 450 000). Small settlements were also found along roads and in an agricultural area in southern Somalia. It was the south that was afflicted by the 1977 epidemic.

The population of Somalia was most heavily concentrated between the Juba and Shabelle rivers in the south and in areas to the south-east of the French Territory of the Afars and the Issas in the north. About 1.5 million people lived in the most heavily populated areas in the south and about 900 000 in the north. The rest were widely scattered over a vast, arid scrub desert in which population densities seldom exceeded 1 or 2 persons per square kilometre. Travel between the northern and southern areas was infrequent. During the dry season, the nomadic population in the north congregated near deep wells, primarily within Somalia; during the March-June rainy season, they travelled south and settled widely over a grassy well-watered plateau area in Ethiopia (Fig. 22.2). In the south, the pattern of movement was more complex. Nomads

Plate 22.1. The unpredictable movements of Somali nomads made the search for cases difficult. Their huts were easily carried on camel-back (A) and quickly erected (B).

located west of the Juba river travelled to more westerly districts and into Kenya in the rainy season. During this period, those living between the two rivers dispersed widely throughout the area because of the hordes of insects, especially the riverine species of tsetse flies, which infested the river banks and localities with standing water. The nomads whose herds consisted only of camels or cattle moved more or less constantly throughout the year. Others, termed "semi-nomads," had mixed herds of camels, cattle, sheep and goats and settled during the crop-growing season to cultivate arable land.

The movements of nomads, particularly in the south, were unpredictable, even from one day to the next. This made it exceptionally difficult to conduct any sort of systematic programme, either of case detection or of vaccination, especially during the rainy season, when roads became all but impassable. The rains fell irregularly, sometimes consisting of scattered localized downpours extending over only a few square kilometres. The different nomadic groups competed for the scarce vegetation and each had several searchers who roamed extensively. When rains fell in an area, the report of a searcher might cause an entire group to dismantle its

camp, pack up its belongings and move 50 kilometres or more over a period lasting several days. Moreover, the nomadic groups, often consisting of only 3 or 4 families, frequently broke up into smaller subgroups for the sake of mobility, and families often shifted from one group to another. Although the women, girls and small children stayed in the camps, the men and older boys accompanied the herds; the younger men, who herded the camels, frequently ranged over great distances.

During the time of the smallpox eradication programme in Somalia, there were 4 other factors which led to substantial movements of population. The first was the seasonal need in the south for large numbers of agricultural labourers, which brought nomads and others from sparsely settled areas to the banana and sugar-cane plantations. The second was severe drought, which occurred throughout the Ogaden desert in 1974-1975 and led to the migration from the Ethiopian portion of the Ogaden of an estimated 200 000-300 000 persons, many of whom were accommodated and fed in refugee camps (Plate 22.2) in Somalia and the French Territory of the Afars and the Issas. The third was the Somali-Ethiopian war, which began

**Plate 22.2.** Laas Dhurre camp, Hargeisa District, Somalia. War and famine drove thousands of refugees out of Ethiopia.

in 1977 and resulted in tens of thousands of refugees fleeing into border areas of Somalia and Djibouti. The fourth was a programme, launched in 1975, to resettle upwards of 100 000 nomads in southern agricultural areas.

Health services in the two countries were much more extensive than in Ethiopia. In Somalia in 1968, there were 21 hospitals and 187 health posts and dispensaries with more than 1300 trained health personnel. In the French Territory of the Afars and the Issas, there were 6 hospitals and 16 dispensaries and a health staff of 450 persons, including 41 physicians. The Somali road network—also more extensive than in Ethiopia—consisted of 2000 kilometres of asphalt-surfaced roads and 4000 kilometres of gravel and earth roads.

### Smallpox and its Control before 1969

As was the case in most countries, reporting systems in Somalia and the French Territory of the Afars and the Issas were poor and data on smallpox are incomplete. Variola minor was said to have been the predominant form during recent decades and, in some areas, health staff differentiated between the more severe cases, which they called "true smallpox", and the less severe, which they called "alastrim". Because cases of variola minor were often not reported as smallpox, this distinction undoubtedly contributed to underreporting. From the available data, it appears that endemic transmission in Somalia ceased in about 1962 (Table 22.1). The French Territory of the Afars and the Issas—at least since 1930—experienced only rare sporadic outbreaks following importations, but 2 outbreaks, in 1959 and 1966, are of special interest. Both resulted from importations from Ethiopia and occurred over a 2-month period. The first consisted of 110 cases with 13 deaths (11.8%), and the second of 52 cases with 6 deaths (11.5%). The two outbreaks and the report of a single outbreak in Ethiopia in 1964 (Teclemariam, 1965) provide the only documentary evidence of the persistence of variola major in Ethiopia or the Horn of Africa after about 1955. Apart from the 1966 outbreak in the French Territory of the Afars and the Issas, during which the disease was imported into Somalia, no cases of smallpox were recorded in either country between 1963 and 1971.

..<sup>a</sup> = data not available.

The infrequent occurrence of smallpox in the French Territory of the Afars and the Issas and the cessation of transmission in Somalia in 1962 could not be attributed to national vaccination campaigns. Both countries offered vaccination for those travelling abroad and conducted localized vaccination campaigns when outbreaks occurred. The French Territory of the Afars and the Issas carried out its first country-wide campaign in 1966, during which 115 000 people were vaccinated; thereafter, campaigns using freeze-dried vaccine were conducted every 3 years, each resulting in the vaccination of 100 000–120 000 persons. Somalia, using a locally produced liquid vaccine until 1966, vaccinated only 20 000–50 000 persons a year, primarily the inhabitants of major towns who required vaccination certificates for travel. In addition, because of outbreaks, special vaccination campaigns were conducted in 1962 near the Kenyan frontier and in 1966 near the border of the French Territory of the Afars and the Issas and in Mogadishu. During the latter campaign, 194 000 persons were vaccinated, but with vaccine of dubious quality; a study carried out in 1967 revealed that only 14% of those given primary vaccination had had successful takes.

Special vaccination scar surveys (Table 22.2) conducted in 1967 by a WHO medical

officer and in 1968 by United States Peace Corps volunteers showed that vaccinal immunity was poor even among the rural settled population of Somalia. It was undoubtedly much lower among the nomads.

Until the early 1960s variolation had been widely practised when outbreaks of smallpox occurred. However, no evidence of active variolation was discovered in either country during the 1970s, although as recently as August 1976, Ethiopian staff observed the practice in a Somali-speaking nomad group in the Ogaden desert in Ethiopia (see Chapter 21).

Despite the low level of vaccinal immunity and the proximity of these countries to Ethiopia, which was heavily endemic, the continuing transmission of smallpox had apparently ceased. Imported cases were few, although, because notification systems were poor, it is likely that more occurred than were reported. Long-sustained endemic spread did not, however, develop, the only reasonable explanation for this being that the susceptible population was too widely dispersed for transmission to be sustained. The long absence of endemic smallpox bred an unwarranted confidence among national and WHO staff alike that the disease would not re-establish itself even if it were imported. Similarly, Ethiopian staff were comparatively unconcerned about smallpox among Somali-speaking nomads in Ethiopia and until 1976 gave little priority to their programme in the Ogaden desert.

### THE COMMENCEMENT OF THE SMALLPOX ERADICATION PROGRAMME, 1969

Because of the smallpox situation in the neighbouring country of Ethiopia, the development of an eradication programme in Somalia was considered important. The

government expressed interest, and a WHO consultant visited the country in January 1968 to formulate a plan of operations. This called for a 3-year national vaccination campaign, from 1969 to 1971, coupled with routine assessment of vaccination coverage, as well as the development of a reporting system and surveillance activities. WHO agreed to provide an adviser, vehicles, equipment and vaccine; to meet the necessary operating costs; and to pay a supplementary per diem allowance for all Somali staff when they travelled in the field. Up to the end of 1976, WHO's annual contribution to the programme was modest (Table 22.3) but adequate, in view of the country's small population.

The plan of operations was similar to many other such plans in the Intensified Programme. It called for vaccination to be performed by mobile teams moving in groups from village to village and from house to house. This would serve to protect the settled population, although little thought was given in the plan to the vaccination of nomads, who comprised half the total population. It was decided simply to vaccinate those who were found at water-holes or encountered by chance when the teams were on their travels. From later observation, it was apparent that only a small proportion of the nomads could have been vaccinated by this approach, a deficiency in the campaign which might have been discovered and corrected if the assessment of coverage had been well conducted. The problem was not pursued until 1977.

The vaccination campaign was slow in starting and never functioned well (Table

Table 22.3. Somalia: expenditure by WHO for smallpox eradication and number of doses of vaccine supplied, 1967-1979

22.4). A WHO smallpox adviser arrived in June 1968 to assist with operations, but the campaign was not launched until August 1969. It began in Mogadishu, where 6 teams with 33 workers took nearly 6 months to vaccinate the city's population. Thereafter, 20 vaccinators began work along the Kenyan border, and in May 1970 a group of 12 workers started to vaccinate people in the north of the country. However, the campaign was suspended in November 1970, when cholera began to occur and the teams were directed to administer cholera vaccine. In June 1971 the smallpox vaccination campaign was resumed and by the beginning of 1974, the teams had completed 2 tours of the country. By the end of that year nearly 3.5 million smallpox vaccinations had been recorded, a number which was approximately equivalent to the population.

The number of vaccinations in relation to population would suggest that a reasonably high degree of vaccinal immunity must have been attained by the end of 1974. However, attempts to confirm this by assessment were never diligently pursued. From information that became available in 1977, it would appear that the coverage in settled populations was at best 60-80%; among nomads in the south, it ranged from 10% to 20%.

During 1974 the smallpox vaccination teams were disbanded and their members dispersed throughout the country initially to participate in a national literacy campaign, and then, after a severe drought in 1974-1975, to help in refugee and relief camps. Finally, at the end of 1975 some of the staff returned to full-time duties with the smallpox eradication programme. At that time, 2 teams of 4 persons began a campaign of both smallpox and BCG vaccination, one team working near border areas in the north and

the other in the south. While vaccinating, they searched for cases. With so few personnel engaged, less than one-third of the country could be visited in the course of a year.

No cases were reported in either the French Territory of the Afars and the Issas or Somalia from 1967 until late 1971. However, between November 1971 and July 1976, the two countries together reported 173 cases, the former reporting 131 cases, of which 16 were believed to have been importations from Ethiopia, and Somalia 42 cases, of which 38 were said also to have been imported from Ethiopia. It is probable that there were other cases, since neither country had an organized notification system or an active programme of case detection. Reporting was further compromised because the cases were of the mild variola minor type and some nomadic groups concealed infected persons to avoid being ostracized by other groups, as was the custom when variola major was present.

The first case to be reported for more than 4 years in either country was detected in mid-November 1971 in Djibouti City in a recent arrival from the north of the Territory (Fig. 22.3). Later investigation suggested that smallpox had been introduced from Welo Province, Ethiopia. Other cases soon followed and by the time the outbreak had ended, on 29 February 1972, 104 cases had been documented. Most of them (79) were found in the city itself; the remainder occurred in 4 smaller rural outbreaks. A triennial mass vaccination campaign, scheduled to commence in January 1972, actually began some weeks earlier, and in a matter of a few months, 117 000 vaccinations had been performed.

In October 1972, another imported case from Ethiopia was detected in the French Territory of the Afars and the Issas, but this time secondary spread did not occur. Also in October—for the first time in 6 years—Somalia reported cases; the 5 patients concerned were said to have been infected in Hararge Province in Ethiopia. No secondary cases were reported.

During 1973, cases were imported into both countries. The French Territory of the Afars and the Issas reported 14 cases: 10 represented importations and 4 were among contacts, 3 of whom were infected while hospitalized. Somalia reported 7 cases, of which 6 occurred in the southern part of the country. Their place of origin in Ethiopia was unknown. As in 1972, all were said to have

Fig. 22.3. Somalia and Djibouti: reported importations of smallpox, November 1971–February 1976.

been detected within a few days after the onset of rash and no secondary cases were reported.

In 1974 the French Territory of the Afars and the Issas reported another 12 cases, of which 2 were importations, the remainder resulting from the subsequent spread of infection. These were the last known cases in the Territory. Nine of the 11 cases in Somalia that year occurred in the southern part of the country, in parallel with a spread of smallpox in Ethiopia from the northern mountainous plateau into the southern Ogaden desert. For the first and only time Somalia reported 4

secondary cases, all close contacts in a single household.

From January 1975 to the end of February 1976, Somalia reported an additional 19 imported cases, many of which were in refugees in drought-relief camps, but no secondary cases were said to have occurred.

In 1975–1976, the Smallpox Eradication unit at WHO Headquarters became increasingly sceptical that the reports submitted to WHO from Somalia were complete or fully accurate. It seemed unbelievable that, between October 1972 and February 1976, Somalia could so quickly detect and contain

38 importations, with secondary spread occurring on only one occasion, given the paucity of staff and the lack of an organized surveillance programme. No other country had been so successful in the rapid detection and containment of imported cases. Moreover, data submitted to WHO regarding the dates of onset and dates of detection for 30 of the cases indicated that 20 were supposed to have been detected within 3 days after the onset of rash; yet even the most experienced clinicians had difficulty in identifying cases of smallpox so early in the course of the disease. Even in countries with an adequate surveillance system, cases were rarely detected and diagnosed until a week or more after onset. The reports from Somalia seemed too good to be true. The fact that some of the cases were first reported to WHO in Geneva through one of the embassies in Mogadishu but were not notified officially to the Organization until questions had been raised with the Somali government did nothing to increase confidence in the official reports.

Meanwhile, in letters from Henderson to the WHO regional smallpox adviser, copies of which were sent to the WHO smallpox adviser in Somalia, repeated attempts were made to obtain additional information about the status of the programme and the occurrence of cases, and advice was offered as to the methods that should be adopted in the investigation, containment and notification of outbreaks. One letter, dated 23 February 1976, is of special interest in view of subsequent events:

"The occurrence of 4 importations into Somalia during the course of only a few weeks is both surprising and alarming. It suggests indeed that many more may occur and unless due care is taken, I believe there is a very real risk that Somalia might become epidemic... I am very concerned that Somalia should not become an endemic area just at that point when we believe the problem in Ethiopia is coming under control. The memory of Botswana becoming reinfected just at that point when the last cases in South Africa were occurring is too fresh!"

Somalia reported a case in February 1976 but no others were notified during the next 6 months. No reports were received from embassy sources, which had, in the past, been reasonably prompt and accurate in forwarding information. In retrospect, greater efforts should have been made during this period to assess the problem through per-

sonal visits but because of the complex logistics of the final phase of the Intensified Programme in Ethiopia and a range of activities concerned with the certification of eradication in many different countries, the attention of WHO Headquarters and regional smallpox eradication staff was diverted from a country which was apparently free of the disease.

At some point in 1976 smallpox became re-established in Somalia. It could not be determined exactly when this occurred, and information about the cases could not be obtained. Political problems played a role in inhibiting surveillance and the reporting of cases. In the Ethiopian portion of the Ogaden desert, the Western Somalia Liberation Front had been formed in the early 1970s and a liaison office set up in Mogadishu. Training camps were established in Somalia near the border with Ethiopia, and guerrilla forces as well as nomads began moving back and forth across the border in larger numbers. In 1976-1977, guerrilla warfare steadily intensified, eventually culminating in the occupation of the Ethiopian portion of the Ogaden desert by the Somali army in July 1977.

### THE SMALLPOX OUTBREAK IN MOGADISHU, SEPTEMBER 1976

After the last known case of smallpox occurred in Ethiopia, on 9 August 1976, 7 weeks passed during which no case was reported from anywhere in the world. Specimens from patients with rash and fever in many countries were received daily by the WHO Smallpox Eradication unit in Geneva and dispatched to the reference laboratories in Atlanta and Moscow. None of them showed evidence of poxvirus until 27 September, when the Atlanta reference laboratory reported the presence of poxvirus in 2 specimens from Somalia. Henderson immediately sent the following cable to Mogadishu:

"POXVIRUS PARTICLES PRESENT BOTH SPECIMENS STOP DIAGNOSIS OF SMALLPOX VIRTUALLY CERTAIN STOP URGENT THAT EVERY CONTACT SINCE RASH ONSET BE FOUND AND VACCINATED INCLUDING ALL HOSPITAL PATIENTS STOP SITUATION MOST CRITICAL SINCE NO SMALLPOX SINCE 9 AUGUST IN ETHIOPIA STOP ESSENTIAL DETERMINE WHERE BOTH PATIENTS WERE EACH DAY FROM SEVEN TO SEVENTEEN DAYS BEFORE ONSET STOP SUSPECT BOTH EXPOSED SAME LOCATION

STOP HIDDEN FOCUS MUST BE PRESENT NEAR BORDER OR POSSIBLY ELSEWHERE STOP THIS COULD BE WORLDS LAST FOCUS STOP ESSENTIAL THIS BE FOUND AND CONTAINED URGENTLY STOP ARITA DEPARTING EARLIEST POSSIBLE FLIGHT TO ASSIST."

Arita departed for Somalia forthwith to help in the investigation, and telephone and telex messages between Geneva and Mogadishu began to be exchanged daily.

By the end of September, 5 patients who had experienced the onset of smallpox between 30 August and 23 September had been placed in an isolation hospital in Mogadishu. The first 2 entered hospital on 1 and 14 September respectively; these were the patients from whom the first specimens had been taken. The remaining 3 were hospitalized between 20 and 25 September.

The 5 patients, ranging in age from 16 to 70 years, were questioned repeatedly by Arita and Somali staff in an effort to determine where they might have contracted the infection. They all claimed to have been living in one or the other of two areas in Ethiopia and said that 8–10 days before the onset of illness they had travelled to the Somali border on foot and thence had taken a bus to Mogadishu, a distance of 400 kilometres (Fig. 22.4). Two patients were said to have reported seeing other people with a similar type of rash in areas of Ethiopia from which they said they had come. The two areas thus identified were situated in the desert, one lying south-west of Dimo, the site of the last known outbreak in Ethiopia, and the other further to the south-east, near the border. The reports were plausible. Ethiopian teams had been actively searching for many months throughout most of the Ogaden except in the province in which the two suspect areas were located. There, search operations had been delayed until August 1976 by guerrilla warfare and were somewhat hampered thereafter.

Arita immediately travelled to the Somali–Ethiopian border to contact WHO epidemiologists working in the Ethiopian part of the Ogaden desert. By conveying to them in detail the information obtained from the 5 patients, he hoped that the focus in Ethiopia might be quickly located and contained. An extensive search in Ethiopia was promptly undertaken by a staff which included 8 Ethiopian sanitarians, 5 WHO epidemiologists and 150 search workers using ve-

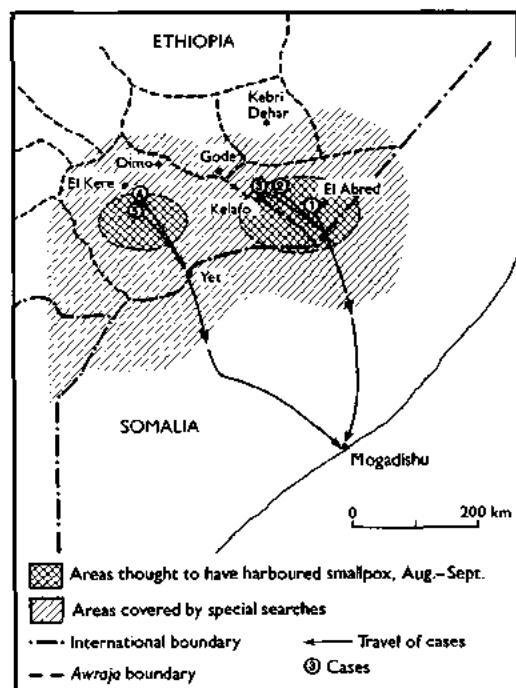

Fig. 22.4. Ethiopia and Somalia: areas thought to have harboured smallpox and areas searched, 1976.

hicles, helicopters and a fixed-wing aircraft. The entire area was searched repeatedly over a 6-month period, but no evidence that smallpox had been present after July 1976 could be found.

A more accurate, although still incomplete, account of what had actually happened did not become available for many months, indeed years. The search for a source of infection in Ethiopia had, in fact, been futile because, by then, endemic smallpox had already become established in Somalia, a fact known both to Somali staff and to the WHO smallpox adviser.

For Somalia at that time to admit to the existence of cases was awkward for both the political leaders and the national health staff. With tension mounting between Somalia and Ethiopia, the periodic meetings of national smallpox eradication staff from the two countries at border posts had become increasingly acrimonious, as each expressed doubts about the quality of the other's programme. In September, Somali programme staff simply did not believe that Ethiopia had become smallpox-free. A letter dated 11 November 1976 from the WHO representative in Somalia to the Director of the WHO Re-

gional Office for the Eastern Mediterranean, reflected the prevailing emotional climate:

"Government authorities have resented the fact that Ethiopia has been declared free from smallpox, almost at the same time as Somalia was declared as the last known infected focus in the world. This is viewed as some kind of international conspiracy and the influx of WHO smallpox experts as adverse publicity for Somalia."

Reports later received by WHO field staff indicated that other suspected cases of smallpox had been hospitalized as early as June 1976, and less definite information suggested that there had been other unreported cases, indeed sizeable outbreaks, earlier in the year. Somali staff had hoped that containment could be achieved without publicizing the outbreaks, thus avoiding the stigma of Somalia's being identified as the last infected country. As in other countries that sought to contain outbreaks while suppressing information about their existence, the outcome was disastrous.

With smallpox known to have been prevalent in Somalia for many months, it is curious that a decision was made, on 14 September 1976, to obtain specimens from 2 patients and to submit them to WHO for laboratory examination. Three events appear to have been responsible: first, the receipt of a letter from Henderson informing Somali programme staff about a projected news conference to announce that the world's last case of smallpox might now have occurred; secondly, the arrival in Mogadishu of Dr Bert van Ramshorst, a WHO smallpox adviser with the Ethiopian programme who had been seized by the Somali border police; and thirdly, the first occurrence of smallpox cases in the capital city. Henderson's letter, dated 30 August, was addressed to the regional smallpox adviser at the WHO Regional Office for the Eastern Mediterranean in Alexandria, and a copy was sent to Mogadishu:

"As the days go by, it seems increasingly possible that the Bale [Ethiopia] case with onset on 9 August 1976 could be the world's last case of smallpox ... my guess would be that it will be difficult to have reasonable confidence about this until late October. When we do reach [that] point, the Director-General would like to make a major announcement with maximum possible news coverage ... Such an announcement conceivably could be made jointly with the Secretary-General at the [United Nations] General Assembly ... one would not wish to make an announcement that there are

no known smallpox foci without having reasonable confidence that another outbreak would not emerge one or two weeks later. We know, of course, that we cannot have full confidence until at least two years have elapsed ... [but] the provisional announcement, which would be highly newsworthy, could come, I believe, as early as late October."

That the programme in Ethiopia might be better than Somali officials had believed was confirmed by Dr van Ramshorst. The report of the WHO smallpox adviser in Somalia, dated 16 September 1976, to the regional director is of interest:

"Dr van Ramshorst crossed into the Somali territory on the afternoon of 8 September 1976 near Abu Duaq. He was detained by border police and handed over to security authorities who brought him to Mogadishu the same night. He was in Mogadishu from 9 to 13 September before RR UNDP [Resident Representative, United Nations Development Programme] was informed about his detention ... During Dr van Ramshorst's stay in Mogadishu, we have made some useful exchange of information ... I was able to arrange a meeting with the Minister. The Minister was favourably impressed with the zeal and enthusiasm demonstrated by Dr van Ramshorst in the pursuance of the objectives of the programme ... for the first time the Somali health authorities have now appreciated the effort that is being put into the programme on the other side of the border."

The possibility that Ethiopia might be free of smallpox could no longer be discounted. The discovery of smallpox cases in Somalia after an announcement by the Director-General of WHO that smallpox appeared to have been eradicated would have been most embarrassing. The concealment of the outbreak in Somalia could continue no longer.

### Initial Containment Measures

Somali programme teams assisted by 2 WHO advisers endeavoured to find the source of infection of the 5 cases and, still believing that it was in Ethiopia or along the Somali side of the border, undertook a 3-day search in border areas in Somalia, from 3 to 6 October 1976, but discovered no cases. They reported that 80-90% of the villagers whom they saw had vaccination scars. A more intensive search was deemed necessary, and 32 staff and a WHO epidemiologist, provided with 4 vehicles, were assigned to the task. The

WHO/J. MAURE

**Plate 22.3.** The WHO smallpox recognition card was abundantly used by the Somali search teams inquiring about possible cases of smallpox.

search began on 9 October and was completed on 2 November. It ranged over an area about 500 kilometres long by 100 kilometres wide but revealed no cases. In all, some 12 000 persons were seen in approximately 30 different villages; 74% had vaccination scars. Of 1200 nomads seen at watering-places, 68% had previously been vaccinated. All denied having seen cases of smallpox for 2 years or more.

Meanwhile, house-to-house night-time searches were conducted in Mogadishu on 18 and 25 October (Fig. 22.5) utilizing 60 programme staff in the northern part of the city, in which the cases had been discovered, and 2000 other staff, including police, to search the other areas.

Cases continued to be admitted to hospital and by the end of October, 20 had been officially reported (Fig. 22.6). The sources of infection of only 10 cases could be documented. Careful investigation, search and vaccination in and immediately around the dwelling of each patient were urgently required. The WHO epidemiologists were skilled in this approach but were not permitted to accompany Somali health staff in visits to houses in the city or in questioning

patients at the hospital. Containment was less than optimum because vaccination was conducted only during the daylight hours, when most adults were away from home. To help in detecting cases, WHO staff proposed that a reward should be offered to anyone reporting a case, but this proposal was not accepted.

The persistence of cases led to a city-wide vaccination campaign extending from 28 October to 15 November, and this was followed on 16 November by yet another night search. Only 9 cases of smallpox were reported in November, and for 8 of them the source of infection could be clearly identified. It was hoped that the outbreak might be coming to an end but, as it was later learned, the notification of cases continued to be suppressed. Smallpox patients were then being admitted to two different parts of the hospital, one in which cases were officially reported and another in which they were not. Officially 34 cases were registered as having been hospitalized in 1976; the unofficial hospital register, not made available until 1978, showed the actual number to have been more than 500.

The continuing failure to discover the source of infection of what was thought to

have been the first 5 importations into Mogadishu was most disturbing at the time. It was claimed that the foci had been in Ethiopia but no evidence of smallpox had been found there since early August. The most reasonable explanation, seemingly, was that the cases had occurred among nomadic groups which had moved elsewhere before the search. With the passage of time, it was thought that such groups might well have penetrated far into Somalia. Search of the border regions in

Somalia had failed to detect cases and none had been reported subsequently by 5 Somali mobile teams then working outside Mogadishu. However, no systematic search had yet been conducted in the 5 other administrative regions of southern Somalia. Accordingly, WHO proposed to the health authorities that such a search should be undertaken, with support from 2 additional experienced WHO epidemiologists who had recently arrived in Mogadishu. A plan was elaborated by Somali and WHO staff which called on WHO to provide 10 more vehicles, to be obtained through emergency local purchase in Kenya, and to cover the necessary local costs. An expenditure of US\$350 000 was envisaged. On 11 November the Director-General of WHO, in a telegram to the Minister of Health, approved the expenditure, ending on the encouraging note that it was to be hoped that the concerted effort over the next 2 months would be sufficiently intensive to identify clearly and to interrupt the links in the chain of transmission. If this proved successful and it could be asserted with confidence that no hidden foci existed, he would plan to make a formal announcement at the January 1977 meeting of the WHO Executive Board that the world's last smallpox foci had been eliminated. The Minister, in his reply three days later, affirmed the government's commitment: "... we shall spare no efforts to mobilize all available resources..." but he pointed out that Somalia would not have had the problem if Ethiopia

Fig. 22.5. Mogadishu: number of reported cases of smallpox, by week of onset, September 1976–January 1977.

Fig. 22.6. Mogadishu: ostensible chain of transmission of smallpox, September 1976–January 1977.

had acted prudently; he requested that US\$2 000 000 should be made available.

Permission to search in the 5 regions was not, however, forthcoming. It was therefore proposed that Ladnyi, at that time an Assistant Director-General of WHO, should visit Somalia early in December to discuss the problem. With Ladnyi's impending visit, permission was given for the WHO epidemiologists to make 1-day visits to each of the regions in the south; later, on 15 December, they were allowed to make such visits in the northern regions. Little could be done in the way of search during such brief visits but at least the WHO staff were thus enabled to make personal contact with the regional health authorities and to discuss the need for case detection—though everyone they spoke to denied that smallpox was present.

As a consequence of Ladnyi's visit, permission was given for WHO staff to visit the hospital regularly with Somali counterparts and to undertake investigations throughout the city. Thereafter, the transmission of smallpox in Mogadishu subsided rapidly. However, despite the visit, WHO staff were not allowed to participate in a search in other parts of the country. The Minister insisted that not less than US\$2 000 000 would have to be provided before a search could begin. WHO staff considered this to be an exorbitant sum; moreover, it far exceeded the amount of money WHO then had at its disposal for smallpox eradication.

Although a national search for cases could not be undertaken, the situation appeared to improve from January to mid-March 1977. In Mogadishu, the vaccination of contacts and close neighbours of patients began to be conducted at night as well as during the day, and on 17 January 1977, the last case was reported. Repeated night searches of the entire city in January and again in February failed to detect further cases. Sanction for an organized national search was finally given on 21 January, during the fifty-ninth session of the WHO Executive Board, when the Director-General, the Director of the WHO Regional Office for the Eastern Mediterranean, Ladnyi and staff of the Smallpox Eradication unit held a private meeting with a member of the Board from Somalia. He agreed that 6 more experienced epidemiologists should be recruited immediately by WHO to serve as advisers in each of 6 regional administrative areas in southern

Somalia and to help in conducting an intensive search commencing late in March. WHO agreed to provide the proposed US\$350 000 in additional funds to cover expenditure on transport and supplies and local costs. It was also agreed that a special meeting would be convened in March to coordinate what was hoped would be final search activities throughout Ethiopia, Kenya, Somalia and the Sudan to confirm that eradication had been achieved.

The development of the programme in Somalia at this time was greatly facilitated by the appointment in February of a new national Smallpox Eradication Programme Manager for Somalia, the knowledgeable Dr Abdullahi Deria, who had just returned to the country from a course of study in tropical medicine. With Dr Ehsan Shafa, of the WHO Smallpox Eradication unit, he immediately set to work to draw up a search plan. So far as WHO staff then knew, only 39 cases of smallpox had been admitted to the hospital in Mogadishu, and although everyone was aware that some additional cases had occurred, it seemed unlikely that a national search would turn up large numbers of outbreaks. To facilitate the detection of cases, Dr Deria and Dr Shafa decided that, beginning in March, a reward of 200 Somali shillings (US\$32) would be offered to anyone reporting a case.

WHO/E. SHAFI

**Plate 22.4.** This man reported a case that proved to be smallpox and received the reward of 200 Somali shillings.

A disturbing event during this period was the discovery on 30 January 1977 of an outbreak in Kenya. The first case had occurred on 26 December 1976 in a Kenyan village near the Somali border, introduced by a young man returning from a religious school in Mogadishu. Shortly after becoming ill, he had returned to Somalia but no one knew where he had gone. Meanwhile, he had infected 4 other persons—his sister and her 3 children. Possible areas in and around Mogadishu were searched, but to no avail. In February, when it was learned that he might have gone to a town 80 kilometres north of the city, a Somali-WHO team investigated this area, but again, neither the patient nor any evidence of smallpox was found. It is not known what relationship, if any, the index case bore to outbreaks which were found subsequently. In part, this was because the government asked that when the 6-month national search was undertaken, cases and outbreaks which had occurred previously should not be documented.

#### **First Coordination Meeting, March 1977**

To coordinate the forthcoming inter-country search programme, Arita, with assistance from Dr Wilfred Koinange, Director of Health Services of Kenya, convened a meeting in Nairobi on 15 March 1977 of health staff from Ethiopia, Kenya, Somalia, and the Sudan. At that time, more than 2 months had elapsed since a case had last been notified. Each of the delegates reported on the nature and extent of his country's surveillance programme and expressed hope that smallpox transmission had been interrupted. Dr A. I. Idris from the Sudan, who was still sceptical, pointed out that, however satisfactory surveillance appeared to be, no link had been discovered between the outbreak in Kenya and the last outbreaks in Mogadishu. To him this indicated that other undetected cases must have occurred, and until the chains of transmission had been clearly identified efforts could not be relaxed. It was a prophetic observation.

The participants all agreed to undertake similar types of search programmes over the succeeding 6 months, involving house-to-house searches for cases and special searches among nomads, the collection of specimens from cases both of chickenpox and of suspected smallpox, and notification through

WHO Headquarters in Geneva of rumours of outbreaks in other countries. Priority would be given to the Ogaden desert area. In Ethiopia a thorough search of the area would be carried out every 4–6 weeks employing 224 search workers, 16 supervisors and 4 WHO epidemiologists, provided with 18 vehicles and 2 helicopters. Kenya planned to utilize 320 public health staff and 64 locally recruited workers with 16 vehicles. In Somalia 300 search workers, 10 Somali supervisors and 7 WHO advisers with 19 vehicles would be deployed. The group agreed to meet again 6 months later to assess the situation and to decide on future action. Staff from Djibouti would also be invited to that meeting to ensure full coordination of all activities throughout the entire area.

#### **EPIDEMIC SMALLPOX IN SOMALIA, MARCH 1977**

Shortly after the Somali smallpox eradication staff returned from the Nairobi meeting, Dr Deria reported to the WHO advisers that 2 cases of smallpox had been discovered in Bakool Region, near the Ethiopian border—the first outbreak to be officially reported outside Mogadishu. A joint Somali-WHO team visited the area and was told that the first patient had been in an Ethiopian village 2 weeks earlier. Ethiopia was immediately notified but investigation revealed no evidence of smallpox in the designated village either at that time or in the past. A few days later, another case was reported from a village much further south but no source of infection could be identified. On 24 March, yet another case was reported. By mid-April there were 29 cases, and more were being discovered daily as the search programme was gradually intensified. Villagers revealed the disturbing information that smallpox outbreaks had occurred outside Mogadishu in 1976, but these had never been notified. Indeed, an outbreak of 17 cases in November and December 1976 was found to have been verified by both the regional medical officer and the WHO smallpox adviser but not officially reported.

Meanwhile, experienced WHO staff members working in India, including Dr M. K. Al Aghbari, Dr W. Hardjotanojo and Mr R. J. Hatfield, were mobilized and sent to Mogadishu in March. However, they were too few to cope with the situation. In April, Arita

### A Unique Approach to Case Detection

In March 1977, the suppression of information and the concealment of cases continued to be widespread despite the new instructions of the Ministry of Health. One of the first to break this barrier was an ingenious Sudanese sanitarian, Mr Abdul Gadir El Sid, who was serving as a WHO consultant. On entering a village for the purpose of investigating suspected cases, he saw several persons with facial pockmarks suggestive of recent smallpox but was confronted with unanimous denial by the villagers that cases had recently occurred. Taking over the vehicle from his driver, he deliberately drove it into deep mud. A large crowd came from the village to help to extricate the car, and among them were 4 persons with active smallpox.

hurriedly flew from Geneva to Mogadishu, and with the agreement of the government immediately took measures to recruit 8 additional WHO epidemiologists to complement the 7 provided by the Organization who were already working there. It was the first step towards a greatly intensified effort (Table 22.5). In April alone, 157 cases were documented in more than 40 outbreaks (Table 22.6). However, the discovery of cases and the containment of outbreaks among

nomads were proving to be extremely difficult. The encampments were often hard to locate in the high scrub; the groups were small, averaging no more than 30-40 persons; and less than 25% remained in a given location for more than a week. Meanwhile, search in Ethiopia was increasingly hampered by guerrilla warfare and border hostilities. The final goal of global smallpox eradication, which only weeks before had seemed imminent, was once again in doubt.

<sup>a</sup> No cases were reported in Bari, Galbeed, Mudug, Nugal or Sanaag Regions.

<sup>b</sup> Although reported in November, all 3 cases experienced the onset of illness before 27 October.

### The Emergency Programme, May 1977

In May 1977, delegates attending the Thirtieth World Health Assembly heard reports on the smallpox situation in Ethiopia, Kenya and Somalia and expressed considerable apprehension. The number of cases in Somalia was increasing each week, and with hostilities between Ethiopia and Somalia escalating, the prospects for control, let alone eradication, were not encouraging. Not only were Kenya and Ethiopia at risk of reinfection, but in the autumn, during the annual pilgrimage to Mecca, other countries would be at similar risk. Since variola minor—the predominant form—was clinically so mild, concern was expressed that pilgrims might travel to Mecca even though they were ill, and while there would spread it to other pilgrims, coming from Asia and other parts of Africa. The Health Assembly accordingly adopted a resolution (WHA30.52), which stated:

"Recognizing that, while smallpox is now reported from only a single country in north-eastern Africa, continuing smallpox transmission in that area represents considerable danger for adjacent countries owing to nomadic population movements...

"REQUESTS all Member States to continue to give financial support to the smallpox eradication programme, either through the Special Account for Smallpox Eradication of the Voluntary Fund for Health Promotion or on a bilateral basis, in order that the last known smallpox foci can be eliminated as rapidly as possible...

"URGES all governments to make full use of the expertise of international and national personnel with experience in smallpox surveillance and in containment measures as may be required effectively to interrupt transmission of the disease..."

Additional resources were urgently required but voluntary contributions from governments would inevitably take some time to become available, and WHO's funds for smallpox eradication were running low. Moreover, at least a year would elapse before vitally needed vehicles could be delivered from the factory. On 16 May WHO telephoned the Office of the United Nations Disaster Relief Co-ordinator (UNDRO) in Geneva to seek help. UNDRO indicated that it would be willing to make a world-wide emergency appeal if Somalia would officially declare the epidemic a disaster requiring the expenditure of resources beyond the country's means (WHO/SE/77.99, Hauge & Wickett).

The agreement of the United Nations Development Programme's Resident Representative in Somalia that the resources requested were appropriate to the emergency was also necessary. A telex was immediately sent to Mogadishu, and on 18 May the government officially declared the situation to be a disaster and appealed for assistance. After a detailed list of urgently needed supplies had been prepared, UNDRO endorsed the request, and on 27 May issued an appeal to possible donors. Within the week, cash donations and contributions in kind amounting to some US\$400 000 were received from Canada, the Netherlands, Norway, Sweden, the United Kingdom and the League of Red Cross and Red Crescent Societies. The total amount provided eventually reached US\$459 750. In addition, Dr William Foege, Director of the United States Center for Disease Control, who was attending the Thirtieth World Health Assembly, offered to assign 5 epidemiologists forthwith to provide assistance over the following 3 months.

To procure and deliver 16 vehicles and tons of camping equipment, transceivers and other supplies, such as tires and spare parts, posed another problem. Two airlines which normally provided a service to Somalia suspended shipments in May because of fear of the outbreak of war. An emergency airlift was required and this was provided by Canada, Sweden and the United Kingdom. Vehicles which had already been delivered to UNICEF for an emergency reserve, plus others in the possession of the United Kingdom government and the League of Red Cross and Red Crescent Societies, were earmarked for use. Procurement and supply staff from UNDRO and WHO, working with their counterparts in various countries, hurriedly assembled materials, and in 4 special flights over the period 4–14 June the whole consignment was delivered. On 8 June the 5 epidemiologists from the USA arrived, and on 9 June the French government delivered by air 3 teams with 2 vehicles and supplies. Four persons from OXFAM, the British private charitable organization, arrived later that month. By mid-June more than 3000 national staff, primarily locally recruited workers, assisted by 23 epidemiologists working for WHO and 52 vehicles, were in the field.

Ježek and Dr B. Kříž had arrived in Mogadishu on 10 May. The former assumed the senior leadership role for WHO and the latter took immediate responsibility for the

emergency operation in Bay Region, the most affected area. On 21 May, the Somali government agreed on a detailed emergency programme to be conducted throughout the 10 regions in the south (later, as additional resources became available, the programme was extended to the northern regions). Sixteen health assistants were trained and designated as regional epidemiologists, operational offices were established in each affected district and all possible health staff were assigned on an emergency basis to search systematically for cases and to vaccinate all persons within a radius of 5–10 kilometres from the site of an outbreak. One or more WHO epidemiologists worked in each region. Regional party secretaries worked with them to mobilize party workers and assistance was offered by the Somali Women's Democratic Organization, the Somali Workers' Organization, and the Somali Youth League.

In Mogadishu the central programme office was reorganized and reinforced with a WHO administrative officer from the Bangladesh programme, a transport and supply officer and, later, a finance officer. In April, the publication of a weekly surveillance report began. Training programmes, launched in May in Mogadishu, were conducted thereafter in every region. Monthly meetings of all senior staff throughout Somalia began in June; they were attended by the Minister of Health and by Arita, who travelled every month from

Geneva for the purpose.

Operations were initially concentrated in southern Somalia. Most of the outbreaks were centred in the area between the Juba and Shabelli rivers, the most fertile and heavily populated area in the country. The area was criss-crossed by watercourses which flowed briefly during the seasonal rains, only occasionally reaching the sea. The rains, from March to June, were heavy in 1977, creating large marshy areas and washing away roads. Searching the areas was difficult because of the lack of maps and the fact that half the population consisted of nomadic peoples who moved frequently over long distances through the dense scrub. Work in the field was further complicated by the need to provide tents to accommodate all but the locally hired nomads and to obtain food to supplement the limited available supplies of milk and goat meat as well as jerrycans for drinking-water. Moreover, because of the prevalence of wild animals, at least 2 persons had to travel together and construct a thorn barricade around their campsite each night. Communication between personnel in the field and the staff in Mogadishu was difficult at best, a problem which could have partly been resolved by employing transceivers. However, with the invasion of the Ethiopian part of the Ogaden desert by the Somali army only a few months away, the use of transceivers was forbidden. Except for this

**Plate 22.5.** A: Rodney J. Hatfield (b. 1949), a WHO administrative officer, established critically needed motor vehicle maintenance and repair workshops in Somalia and Bangladesh. B: Bohumir Kriz (b. 1936), a veteran WHO epidemiologist from the smallpox eradication programmes in Asia, assumed responsibility in May 1977 for emergency operations in Bay Region, the epicentre of the smallpox epidemic in Somalia.

### Vehicle Maintenance in Somalia

The availability of serviceable vehicles was especially vital in Somalia, in which the population was sparse and distances were great. When the emergency programme began in May, only 19 vehicles were in use, 11 of which were more than 5 years old. By July, a fleet of 50 4-wheel-drive vehicles was in operation. To oversee their maintenance and repair, Mr Rodney Hatfield, a veteran of smallpox eradication programmes in India and Bangladesh, was brought to Mogadishu. A valuable paper (WHO/SE/80.155, Hatfield) documents the problems of transport operation and the solutions adopted.

An initial difficulty consisted in obtaining spare parts. This was partially alleviated when substantial stocks, consigned to WHO programmes, were found in the Mogadishu customs office; some had been left in the stores for as long as 3 years. Additional orders were placed for delivery by sea and air. They included special 10-ply truck tires which were required because of the thorn scrub and the frequency of punctures.

Until February 1978, commercial garages had repaired and maintained vehicles for a negotiated price. The expenses were reduced when a WHO workshop was established in February, but even then it proved more costly than had been expected to keep the vehicles on the road. Mr Hatfield found that the servicing of a vehicle cost US\$70 per 1000 kilometres for the first 48 000 kilometres and US\$120 per 1000 kilometres for the next 42 000 kilometres. Over 100 000 kilometres, the total costs of labour and spare parts began to approach the cost of the vehicle. By the time vehicles had logged 150 000 kilometres, the cost of maintenance and repair was prohibitively high, making them unacceptable for unrestricted service.

restriction, government staff supported the programme, permitted travel to any area and made adequate supplies of petrol available.

A complete search was planned to take place twice a month from May to December in all high-incidence areas, once a month in low-incidence areas, and every other month in areas thought to be free of smallpox. The search programme required ingenuity in planning if all or even most nomadic groups were to be found. Gradually, a routine was established which required, first, the preparation of a sketch-map so that specific areas with landmarks could be identified and assigned to each search group. In settled areas, conventional approaches were adopted in which workers displayed the WHO smallpox recognition card and asked about possible cases at each house and in schools, markets, health units and tea-shops. In such areas, one worker could visit from 50 to 100 houses per day. For the nomadic areas, other methods were required. The initial, and simplest, approach consisted in assigning to each area of 10–15 square kilometres a literate health worker from the region and a nomad familiar with the surroundings. By inquiring in settled villages and by sighting smoke from morning camp-fires and finding the fresh faeces of domestic animals and other tracking signs,

they endeavoured to locate each nomadic group within the area. Supervision of this type of search proved difficult, however, and even for nomads who knew the area, it was not easy to locate the groups because of the high scrub and the unpredictable nomadic movements. A second approach, termed the "drop and move" method (Fig. 22.7), consisted in transporting 2-person teams to points along a road and instructing them to identify and question all groups of nomads encountered during a journey of 50–150 kilometres on foot across the desert to a known landmark. This method provided greater certainty that a geographical area had been covered, but the workers were almost as difficult to supervise. As the programme progressed, and larger numbers of staff became available, a technique called the "criss-cross" search evolved. This required teams to move each day from one landmark to another across a defined area during a 3–5-day period. The search was designed in such a way that the teams would cross each other's paths at different times. Landmark check-points (usually villages) were visited by more than one team on different days, thus permitting each team to check on the work of others.

Vaccinal immunity among nomads was often found to be as low as 10%; therefore, to

**Plate 22.6.** Vladimir Zikmund (b. 1925) worked as a WHO epidemiologist in many southern Indian states from 1971 to 1975 before joining the emergency effort in Somalia.

diminish the probability of continuing transmission should smallpox cases recur, vaccination was initially offered by all search teams. In most areas, it was readily accepted, but in others the nomads fled into the bush, thus precluding their being examined for possible smallpox. For this reason vaccination was suspended in some areas except when outbreaks were found. Among both Somali and WHO staff, the efficacy of combining vaccination with the search for cases was frequently debated, and the practice differed somewhat from area to area. It soon became apparent, however, that the epidemiology of variola minor in Somalia was different from that observed in other parts of the world and differed significantly from that of variola major. Outbreaks in small groups did not terminate quickly but, rather, persisted for long periods among comparatively small nomadic bands. On 5 occasions, smallpox was found to have persisted for 3 months or longer in groups of less than 100 persons

**Fig. 22.7.** Somalia: smallpox search methods. Surveillance workers were expected to walk 15–20 kilometres a day.

Table 22.7. Somalia: prolonged transmission of smallpox among groups of nomads

Outbreak	Population of nomadic group	Number of cases	Number of days between first and last cases
1	55	14	163
2	44	19	155
3 <sup>a</sup>	35	24	152
4 <sup>a</sup>	98	20	106
5	75	23	95

<sup>a</sup> Outbreaks 3 and 4 were interrupted by containment.

(Table 22.7). Because of the difficulties of locating such groups and keeping them under surveillance, the decision was made to vaccinate wherever a search was conducted so as to increase the overall levels of vaccinia immunity. This, it was hoped, might serve to retard or stop transmission more quickly. Vaccination scar surveys performed in the south showed levels of vaccinia immunity of 70% or higher by August 1977 and 90% or higher by September. Only 141 days after the emergency programme began, the last known case of smallpox occurred.

Outbreak-containment practices in settled areas were similar to those which had evolved during the programme in Asia. The patient was isolated, a list of village residents was

compiled and all were vaccinated, and a team was posted to the village until the patient recovered in order to vaccinate visitors and to conduct continuing search and vaccination within a radius of 5–10 kilometres. Major differences of opinion arose, however, among both Somali and WHO staff as to where the patient should be isolated. Traditionally, patients in Somalia had been isolated in camps situated, in some instances, as far as 100 kilometres from their homes. Adult patients and their families, especially among the nomads, often objected to this practice; in consequence, cases went unreported and sometimes were hidden from search teams. During the early phases of the emergency programme, few of the isolation camps were well organized or provided adequate food or shelter. Accordingly, many patients who suffered from the mild illness characteristic of variola minor decided to leave the camps before recovery and, because they were inadequately guarded, did so with ease. Moreover, procedures to ensure the vaccination of family members who accompanied patients with smallpox or other skin infections were lax. As a result, the isolation camps, like hospitals in other countries, initially played an important role in disseminating smallpox.

### Observations on Surveillance among Nomads

Dr B. Kříž, an epidemiologist from Czechoslovakia who had worked previously in Asia, made a number of interesting observations regarding surveillance techniques among nomads.

In bush areas in which nomads were semi-permanently settled, he discovered that they were usually easily located. Inhabitants of the nearest villages were generally well informed as to where and how many nomads were settled nearby. Village headmen, members of the village political committee and shopkeepers could provide this information. Because even relatively small areas of the bush—say, 10 square kilometres—had their own names, the nomads could be located if a map were prepared which showed the names of such places, water-holes, tall trees and roads.

In areas only temporarily inhabited during the dry season, the problem was different because the nomads were constantly on the move and there were few settled inhabitants. In places where water-holes were scarce, a well-motivated "government water-hole watchguard" was extremely useful. In some regions, however, water-holes were so numerous that water-hole surveillance was neither practicable nor useful. Market searches were also of limited value. Frequently, only female nomads visited the market but they were not easy to converse with and usually avoided giving information. In such areas, the so-called "criss-cross" technique of search (see Fig. 22.7) was essential.

To monitor nomadic movement and surveillance, it was found useful to give to the headman of a group a small WHO smallpox recognition card with the name of the place and the date when the card was given. This was widely accepted, and as its value in assessing search activities became apparent a specially designed durable card was prepared.

The alternative to isolating the patient in a special camp was to isolate him in his house, as had been the practice in Asia. In settled areas, this could be done using vaccinators as watchguards to ensure that the patient remained in the house and that all visitors were vaccinated. The task was much more difficult with nomads, who moved their camps every week or two. Moreover, the custom of visiting the sick contributed to the spread of smallpox. Hence, a special study was conducted in nomadic areas to determine what procedure would be the most culturally acceptable (Foster & Deria, 1983). It was decided that the best solution would be to construct a *haro*—a circular barrier of thorn bushes normally used to hold and protect animals at night. Accordingly, in most areas patients were isolated in a *haro*, 10–20 metres in diameter, containing a lean-to shelter and latrine. From funds provided by WHO, each patient was given 5 Somali shillings (US\$0.80) a day as an incentive to remain in the shelter, and 2–4 members of the nomadic group were paid 5 Somali shillings a day to build the *haro*, to enforce isolation, to provide food and water

and to vaccinate those at the encampment. When the nomads decided to move, a surveillance agent travelled with them in order to detect any additional cases and to ensure that any persons with whom they came in contact were vaccinated.

In some areas, isolation camps continued to be used but conditions in them were improved and supervision was strengthened. Patients were found to cooperate more readily if, on discharge, they were given new clothes—a practical public health measure because it permitted the old clothes to be burned, thus averting the risk of the spread of infection by fomites. Moreover, as one observer noted, the new clothes served as “a moving poster” which promoted the use of the isolation camps.

#### The Epidemic, March to October 1977

The epidemic, first recognized in mid-March, rose to a peak in June (Fig. 22.8). Although reports had been suppressed until March, it did not appear that the smallpox

T. S. JONES

**Plate 22.7.** A Somali guards the entrance to a hut in which a nomad with smallpox is isolated. These huts were built away from the encampments and enclosed by a thorn-bush barrier to keep out wild animals as well as visitors.

incidence in January and February had been high. The rise in incidence coincided with the beginning of the March rains, when nomadic movement greatly increased. A 15-day religious festival in March held in southern Bakool Region, which was attended by more than 15 000 persons, contributed to the spread. This area, with the adjacent Baidoa

District in Bay Region, became the epicentre of the epidemic (Fig. 22.9) and 4% of the population contracted smallpox. The number of reported cases increased sharply in April and May, when the information spread rapidly that a reward was being given to anyone reporting an outbreak of which the authorities were unaware. In many areas, two-thirds of the outbreaks came to light in this manner, the remainder being discovered by teams during search or being reported by government officials.

The number of new outbreaks occurring during April and May far exceeded the capacity of the few advisers and an as yet untrained staff to cope with them. With the declaration of the emergency in May and the influx of personnel and resources in June, the epidemic began to come rapidly under control. As political leaders and numerous volunteers actively participated, the interval between the onset of the first case and the detection of outbreaks decreased, as did the interval between the first and last cases in the outbreaks (Table 22.8). The outbreaks were more effectively contained, and, in consequence, became smaller (Table 22.9) and

### Persistent Transmission among Nomads

Dr Stanley Foster, formerly a senior WHO smallpox adviser in Bangladesh, with Mr Abdul Gadir El Sid, previously with the eradication programme in the Sudan, painstakingly documented the movements of one group of 44 nomads from June 1976 to the end of August 1977 (Foster et al., 1978). During this period, the nomads ranged over an area of about 70 kilometres by 35 kilometres (see illustration below). Only 7 members of the group had previously been vaccinated. In February 1977, the first case of smallpox occurred. The disease spread slowly among the group with only 1 or 2 cases in a generation of transmission. In all, 19 cases occurred over a 5-month period.

#### *Somalia: Mandeelo group migration, Bakool Region, June 1976–August 1977*

soon disappeared from the larger towns and villages (Table 22.10). In April 50% of the outbreaks occurred among nomads, a proportion which rose to 75% in June and to more than 90% in July. In all, 570 out of 843 outbreaks for which data are available were among nomads.

Table 22.10. Somalia: number of smallpox-affected localities, by population size and month, 1977

<sup>a</sup> When locality was first affected.

By late August surveys showed that 77% of the settled population and 70% of the nomads knew of the reward for reporting a case, and the epidemic had subsided to very low levels. At the end of October the last outbreak was contained. In all, 3229 cases had occurred in 947 different outbreaks. All except 5 of the cases during 1977 were outside Mogadishu. Most cases occurred in the Bay Region; few were detected outside the area between the Juba and Shabelli rivers or along their banks. Only 1 outbreak, a documented importation from southern Somalia, was discovered in the country's 6 northern regions (Fig. 22.9).

### Surveillance among Nomads in Adjacent Areas of Ethiopia

With outbreaks occurring so close to the border with Ethiopia, and nomads moving freely from one country to another, surveil-

lance in Ethiopia became vitally important. Despite heightening tension between Somalia and Ethiopia and increased guerrilla warfare, Ethiopian staff continued work in the Ethiopian part of the Ogaden desert up to the end of June 1977. Between April and June, they investigated 32 rumours of cases reported by Somali staff and 136 rumours emanating from within Ethiopia. Most of these rumoured cases (96), on investigation, proved to be obvious cases of chickenpox or other skin infections. Numerous specimens were obtained but none contained variola virus. In July the Somali army occupied most of the Ogaden, and at this time surveillance by Ethiopian health staff ceased.

Surveillance in the Somali-occupied areas of the Ethiopian Ogaden provided a new challenge. Neither Somali health staff nor WHO epidemiologists were permitted into this area by the military. No surveillance was carried out for almost 2 months, but late in August an innovative "across the border" surveillance programme began. Five headquarters posts were established at different points along the border, each with Somali staff and an experienced WHO adviser: Dr M. N. El Naggar (Egypt), Mr Carl Hasselblad (USA), Dr Bert van Ramshorst (Netherlands), Dr J.-P. Ryst (France) and Dr J. S. Weisfeld (USA). Because some of the WHO staff had worked in this area previously as advisers to the Ethiopian programme, it was comparatively easy for them to recruit as supervisors and searchers the people who had previously been employed in the Ethiopian programme. With maps already available to them, it was possible to design a systematic search programme which was conducted largely on foot. Specimens were collected from all persons experiencing fever with rash and the specimens were brought back to the border posts. Between August 1977 and February 1978, 410 rumours were investigated and 151 laboratory specimens were obtained.

Independent assessment of the extent of activity of the search workers required different methods. One approach was to require each supervisor and search worker to keep a daily log-book in which he listed all the places visited and entered the full details of each person with fever and rash. The validity of the entries was then checked by other staff. On other occasions, workers were instructed to leave in each village coded WHO smallpox recognition cards. A second

group visited the villages at a later date and retrieved them.

Most of the local staff in this programme performed well but some of them believed that their employment had to be justified by the discovery of rumours of smallpox cases which they would then have to investigate. Thus, throughout this period, there was a continuing and alarming flow of reports of possible cases of smallpox. Fortunately, however, an independent check could be made through an examination of the specimens obtained. None revealed the presence of smallpox.

Towards the end of 1977, concern about military security eased, but diplomatic restrictions prevented WHO staff from officially entering the areas of the Ogaden occupied by the Somali army. However, the group engaged was more concerned about smallpox than about diplomatic protocol and took it upon themselves to travel extensively throughout the Ogaden, beginning in November 1977. Areas in which outbreaks had been reported by the search workers were revisited and confirmed to be free of smallpox. This activity ceased in March 1978, when fighting again increased, causing large numbers of refugees to cross into the border areas of Somalia, many being housed in refugee camps. In a thorough investigation of these camps no one was encountered who had seen cases of smallpox since 1974 (Table 22.11).

The report describing in detail the extent of surveillance activities in the Ethiopian Ogaden during the period of occupation by the Somali army was to prove invaluable to the International Commission for the Certification of Smallpox Eradication in Ethiopia. However, even as late as October 1979, the report was considered politically sensitive and its distribution was restricted to only a few people. This caused some individuals, who had access only to publicly available

Table 22.11. Somalia: results of survey of refugee camps, February 1978

information, to question the Commission's ability to be certain of the status of the Ogaden.

### **The Last Smallpox Outbreak, October 1977**

By the end of September 1977, the optimistic view prevailed that the discovery and containment of the world's last smallpox outbreak were at hand. On 26 September, the second intercountry coordination meeting was convened in Nairobi with representatives from Djibouti, Ethiopia, Kenya, Somalia and the Sudan. All these countries pledged a continuing intensive effort to achieve the elusive goal of eradication. At that time there were only 29 villages in Somalia known to be infected, of which 21 had active cases. Heavy rains again prohibited the use of vehicles throughout much of the area, but with large numbers of staff available it was possible to travel by foot or on camels and donkeys in carrying out the work of search and containment. Meanwhile, search in Ethiopia and Kenya continued but no cases were found.

Between 1 and 23 October, 5 more outbreaks were discovered in southern Somalia, of which 3 consisted of only a single case;

the date of onset of illness in the last patient was 18 October. With a growing recognition that each outbreak contained might be the last, staff worked with an intensity never before attained. A special team arrived to make a documentary film of the programme, later released by WHO and entitled "The Search". Finally, on 31 October, yet one more case was discovered, not among nomads but in the busy regional port of Merca, a town of 30 000 inhabitants (Deria et al., 1980). The patient should have been protected by vaccination long before; after becoming ill he was in face-to-face contact with tens, perhaps hundreds, of people.

As in many other countries, the last outbreak was unusual. The patient, Ali Maow Maalin, was a 23-year-old cook who had become ill with fever on 22 October and developed a rash on 26 October. Although previously employed as a temporary vaccinator in the smallpox eradication programme and more recently as a cook in a hospital in Merca, he had never been successfully vaccinated.

On 12 October, 2 smallpox patients from a nomad encampment, some 90 kilometres from Merca, had been sent at night by vehicle to an isolation camp near the town. The vehicle stopped at the Merca hospital to seek

**Plate 22.8.** Participants in the second intercountry coordination meeting, Nairobi, 26-28 September 1977. Left to right, front row: Girma Teshome (Ethiopia), R. O. Hauge (WHO), Tesfaye Temelso (Ethiopia), Unidentified participant, M. A. Strassburg (WHO), D. W. O. Alima (Kenya), Unidentified participant; middle row: E. Shafa (WHO), B. O'Keefe (Kenya), P. directions and Mr Maalin volunteered to accompany its occupants to the smallpox office, some 100 metres away. One of the 2 patients, a 6-year-old girl, was severely ill and died 2 days later. Mr Maalin was exposed for only a few minutes.

On 22 October he felt feverish and left the hospital for his home, about 200 metres away, in a densely populated area of Merca. During the next 3 days he was visited by many friends and neighbours as well as by hospital employees. He was admitted to the hospital on 25 October with a presumptive diagnosis of malaria, and received numerous visitors, walked freely through the hospital and even went outside the compound to obtain his salary payment. On the following evening he developed a rash which was diagnosed as chickenpox, and on 27 October he was discharged. Feeling ill, he remained at home although, again, he received many visitors. By 29 October he suspected that he had smallpox but, fearing to be sent to the isolation camp, did not inform the authorities. On 30 October, a male nurse at the hospital reported Mr Maalin to the regional health superintendent and to the smallpox eradication staff, who confirmed the diagnosis and sent Mr Maalin to the isolation camp. Unlike the cases of recent months, almost all of which had occurred among small isolated groups of nomads with few close contacts, Mr Maalin had been in contact with numerous people, only some of whom could be identified by name.

The hospital was immediately closed to new admissions, all patients were vaccinated and quarantined at the hospital, all health staff were vaccinated, warning signs were placed around the compound, and a 24-hour police guard was posted. Vaccination teams, consisting of 2 smallpox eradication staff, a policeman and a local political leader, listed by name and vaccinated everyone in the 50 houses surrounding Mr Maalin's home and later in the 792 houses comprising the ward in which he lived. Teams then undertook a search of the entire town each week during the succeeding 6 weeks. With police assistance, a check-point was established on the road into Merca and 3 check-points were set up on footpaths also leading into it so that all persons leaving or entering the town could be stopped and vaccinated. In all, 54 777 persons were vaccinated during the 2-week period from 31 October to 14 November. Meanwhile, meetings were held throughout Merca

to inform the general public of the outbreak and to stress the need to report cases with rash and fever. The reward of 200 Somali shillings for reporting a case was widely publicized.

Efforts were made to identify all the personal contacts of Mr Maalin as well as those who had been in the same building with him at any time during his illness. In all, 91 face-to-face contacts were identified; 58 had been successfully vaccinated within the preceding 3 years; 21 had been successfully vaccinated more than 3 years earlier; and 12 had no vaccination scar. Of these 12, 6 were hospital employees, 5 were hospital patients or visitors and 1 was a personal friend. It was possible to get in touch with virtually all these people within 24 hours, although some lived as far as 120 kilometres away. They were vaccinated and placed under surveillance for 18 days, and their temperatures were taken daily in order to detect any illness as quickly as possible. Five persons under surveillance developed fever during this period and were isolated in their homes but none developed rash. Seventy other persons were identified who had been in the hospital at the same time as Mr Maalin but did not recall seeing him. All had been vaccinated previously; none developed fever during the surveillance period.

Subsequently, a house-to-house search was conducted each month for 5 months throughout the entire Lower Shabelli Region, in which Merca is situated. No further cases were found.

Finally, on 29 December 1977, 2 months after Mr Maalin had first become ill and a country-wide search for cases had been completed, it was decided that the Merca outbreak—the last one remaining on the list of pending outbreaks—could be removed from the list. Then began a 2-year period of intensive surveillance throughout the countries in the Horn of Africa to confirm that eradication had been achieved. Because of the discovery of 2 hitherto unknown foci following apparently smallpox-free intervals of 7 weeks or more (late in September 1976 and in March 1977), the surveillance was diligent. However, the Merca outbreak proved to be the last naturally occurring outbreak and Ali Maow Maalin's illness the last case.

#### MORBIDITY AND MORTALITY DATA, 1977

Data on the age of onset and outcome of illness are available for 3022 of the 3229 cases

Table 22.12. Somalia: reported number of cases of smallpox, by age group, 1977

<sup>a</sup> Details are not available for 207 other cases reported in 1977.

that occurred in Somalia in 1977. The age distribution of cases is especially interesting in that it parallels closely the age distribution of the population at large (Table 22.12). This finding might be expected in a population with little immunity either from smallpox or from vaccination. As has been noted previously, most cases occurred among nomads whose vaccinal immunity was not more than 10-20% when the epidemic began, and although the level of vaccinal immunity rose to more than 90% by September 1977, most cases had already occurred by then. Facial pockmark surveys conducted in 1978 revealed that for most southern Somali nomads smallpox was a new experience, the last large outbreaks having occurred in 1938, nearly 40 years earlier.

Only 13 deaths were recorded—a case-fatality rate of 0.4%, characteristic of variola minor. Six of the 13 individuals who died were infants less than 1 month old, 1 was a case of fetal variola, 4 were children between 1 and 6 years of age, 1 was a 49-year-old man, and 1 was a 90-year-old woman. None of them had ever been vaccinated.

## CONCLUSIONS

From the time the Intensified Programme began, smallpox eradication staff had speculated as to where the last case might occur—no one had expected that it would be Somalia. Rugged, mountainous areas with a paucity of health services, such as Afghanistan or Ethiopia, or densely populated areas, such as Bangladesh or India, in which smallpox spread very rapidly, appeared to be

far more likely possibilities. Somalia, with its sparse population and a more extensive network of health services than many other endemic countries, was an improbable candidate. This opinion was reinforced in 1974, when programme staff reported that the second country-wide vaccination campaign had been completed and that the total number of vaccinations performed during the two campaigns was equivalent to the population of the country.

In retrospect, the epidemic in Somalia could and should have been prevented. The first mistake was the assumption by both national and WHO smallpox eradication staff that continuing transmission of smallpox would be difficult, if not impossible, among pastoral nomads in the sparsely populated Ogaden desert. At the time, the assumption seemed reasonable. Somalia, after all, had become free of smallpox in 1962, in the absence of any national vaccination campaign, and at a time when the health services were using a poor-quality thermolabile vaccine and the numbers of people vaccinated were comparatively few. Because of this, the Ethiopian programme had concentrated its best staff and the bulk of its resources in highland areas rather than in the Ogaden. However, because of natural population growth, an augmentation of the normal nomadic population by refugees, and an increased concentration of people at feeding-camps and water-holes on account of warfare, drought and famine, the potential for continuing transmission of the virus was greater than it had been before. The second mistake was the failure to provide better WHO support to Somalia in strengthening its surveillance programme, at least after 1972, when importations began to be reported. Other activities were assigned a higher priority, in part because of the belief that transmission in Somalia could not be long sustained, especially after its extensive vaccination campaign, and in part because of the need to devote all possible resources to the intensified programmes that had begun in Asia in 1973 and in Ethiopia in 1975. The third mistake was the suppression of notifications by Somali programme staff and even the WHO smallpox adviser on the grounds that they were facing only a minor problem, which could be contained without officially acknowledging it. The staff's lack of experience in the investigation and control of outbreaks because of the long absence of

endemic smallpox, coupled with its inability to request assistance in a situation that had not been reported, permitted a localized problem to grow into a major epidemic. The outbreak was centred in an area which, through resettlement and agricultural development, had become steadily more populated. Few cases of smallpox had occurred in the area for perhaps 40 years and an ineffective vaccination campaign, inadequately assessed, had reached only a small proportion of the inhabitants.

When the problem was finally acknowledged and an emergency declared, only 141 days were to elapse until the last case was

detected and the outbreak contained. The emergency programme, conducted under the most difficult conditions, was as well executed as any national plan of operations in the Intensified Programme. A determined Somali staff aided by experienced WHO advisers worked day and night, drawing on the experience of 10 years of field activities and motivated by the imminence of the ultimate goal of global eradication. And so the final chapter was written: Ali Maow Maalin represented the last case of smallpox in a continuing chain of transmission extending back at least 3000 years.

### INTRODUCTION

In the preceding 11 chapters we have systematically reviewed the elimination of smallpox from the 31 countries in which it was endemic in 1967 and 2 other countries (Botswana and the Sudan) in which endemicity was re-established after 1967. Because smallpox was endemic in many parts of the

world in the 1960s and early 1970s, cases continued to be imported into smallpox-free countries. The annual numbers of smallpox cases in most of the larger countries between 1920 and 1958 are tabulated in Chapter 8. The year in which smallpox was last endemic in each of these countries is indicated in the tables; cases occurring after that year were due to importations. This chapter is con-

<sup>a</sup> Thirteen countries; see Table 23.2.<sup>b</sup> One outbreak in the Federal Republic of Germany started in 1958 but continued into 1959.

cerned with a more detailed description and analysis of outbreaks of smallpox that occurred in industrialized non-endemic countries after 1958, and in non-endemic countries of Africa, South America and Asia after 1966, when reasonably complete information first began to be compiled.

In the industrialized countries a total of 37 outbreaks due to importations from endemic areas were reported between 1959 and 1974: 34 occurred in 13 countries of Europe, 1 in Canada, and 2 in Japan (Table 23.1). In addition to importations by infected persons, there were 3 laboratory-associated outbreaks in the United Kingdom between 1966 and 1978. These are comparable to importations from endemic countries in that they were introductions of smallpox infection into a smallpox-free country; they are described in the last section of this chapter.

A notable feature of this period, compared with earlier times (see Chapters 5 and 8), was the absence of transfers of smallpox between the Eastern and Western Hemispheres, and the rarity of intercontinental importations other than from the Indian subcontinent to Europe (Fig. 23.1). This is surprising, in view of the vast volume of international traffic (4

million air passengers in 1948, 46 million in 1966, and over 400 million in 1975) and the much greater speed of travel by air than by sea.

As the Intensified Smallpox Eradication Programme proceeded, more detailed information was collected about cases throughout Africa, South America and Asia, and as a result of this effort, many outbreaks were recognized which were due to transfers across national boundaries in each of those continents. Most of these importations were contained, but some had serious consequences, leading to the re-establishment of endemic smallpox in the Sudan (1968), Botswana (1971), Bangladesh (1972) and Somalia (1976). An importation from Afghanistan into Iran in 1970 led to a large epidemic which was not terminated until 1972, and spread from Iran to Iraq, then to the Syrian Arab Republic, and from Iraq to Yugoslavia.

Excluding the laboratory-associated incidents, the 34 outbreaks in Europe produced 573 cases, of which 90 were fatal. Although the number of cases was extremely small compared with the number occurring in the endemic countries (perhaps some 50 million cases annually in the mid-1950s), health officers and the general public in the industrialized countries feared smallpox more than any other of the diseases then primarily indigenous to the developing countries.

Importations into Europe and Japan did not cease until 1974, when smallpox had been eliminated from most countries of Africa, from Indonesia, and from large areas of India and Pakistan, including most of the larger cities.

### CRITERIA FOR DEFINING NON-ENDEMIC COUNTRIES

Apart from the industrialized countries, in which importations had been recognized as such from the 1940s or earlier, few efforts were made until 1967 to classify countries as having endemic smallpox or as being smallpox-free. All countries, by international convention, were supposed to report the occurrence of cases of smallpox promptly to WHO, but not all did so, nor were the reports that were received investigated to determine their validity. With the establishment of the Intensified Smallpox Eradication Programme, a deliberate attempt was made to distinguish countries in which smallpox was endemic from those that were free of the disease. Many

errors in reporting the existence of smallpox, and many instances of failure to report the disease, were discovered. After considerable inquiry, 31 countries or territories were eventually categorized as harbouring endemic smallpox in 1967 (see Chapter 10).

Between 1959, when the global smallpox eradication programme began, and 1967, a number of countries of Africa, South America and Asia which were thought to be non-endemic reported a few cases each year—too few to represent accurately an endemic situation with continuing transmission. Before 1967 few of these outbreaks had been further investigated, and it was impossible to determine whether they were due to occasional importations or represented underreported endemic smallpox, or, indeed, whether they were fictitious events reported as a result of clerical or diagnostic error.

Because of uncertainty as to whether countries in Africa, South America and Asia were indeed free of smallpox, and because reporting had been unsatisfactory and importations had rarely been fully documented, discussion of importations into these countries will be brief, and restricted, for the most part, to the period after 1967.

### THE SIGNIFICANCE OF SMALLPOX IN NON-ENDEMIC COUNTRIES

Two aspects of smallpox in non-endemic countries were relevant to the global strategy of smallpox eradication: the actions taken by the countries themselves and those taken by WHO.

#### Actions Taken by the Non-endemic Countries

Before about 1970, almost all industrialized countries regularly vaccinated a large proportion of their population and enforced the requirement stipulated in the International Health Regulations that international travellers should hold valid certificates of vaccination. These measures were pursued with varying degrees of diligence in different countries. In the USA, for example, most children were required to show evidence of vaccination at school entry and the vaccination rate in the population as a whole exceeded 95%. In the United Kingdom vaccination was encouraged but not enforced,

except for international travellers, and only about 60% of the population were vaccinated.

#### *Vaccination certificates*

Many countries placed considerable reliance on the examination of certificates of vaccination, spending much money on checking them and complaining about falsified certificates. However, there were several deficiencies in the certification system. For example, vaccination certificates were regularly examined at most—but not all—European airports. This was less of a problem in Canada and the USA, in which airport health officials were rather more rigorous in asking all arriving passengers where they had been in the preceding 14 days and requiring a valid vaccination certificate from all those who had been in a smallpox-endemic country during this period.

With regard to vaccination certificates, there was much discussion of the need to examine the results of vaccinations 7–9 days later to confirm whether these had been successful, and to require a repeat vaccination if they had not. Few appreciated that much of the vaccine used, especially in endemic countries, was of low potency, and that the failure of a first attempt often resulted in a second vaccination with equally poor vaccine. However, certificates did not require that the results of a second primary vaccination should be examined.

The principal value of vaccination certificates probably lay in encouraging most travellers to be vaccinated before they left their own country. Most intercontinental travellers were from non-endemic countries, and although they were in fact responsible for the majority of importations into European countries (see the next section), the number of incidents might have been much higher had there been no requirement for vaccination certificates.

#### *Control of outbreaks*

In accordance with the philosophy of smallpox control then prevalent (see Chapter 9), industrialized countries in the 1950s and early 1960s usually responded to the discovery of an importation of smallpox by mounting a large vaccination campaign, in parallel with efforts to identify contacts and vaccinate and isolate them. For example, in the outbreak

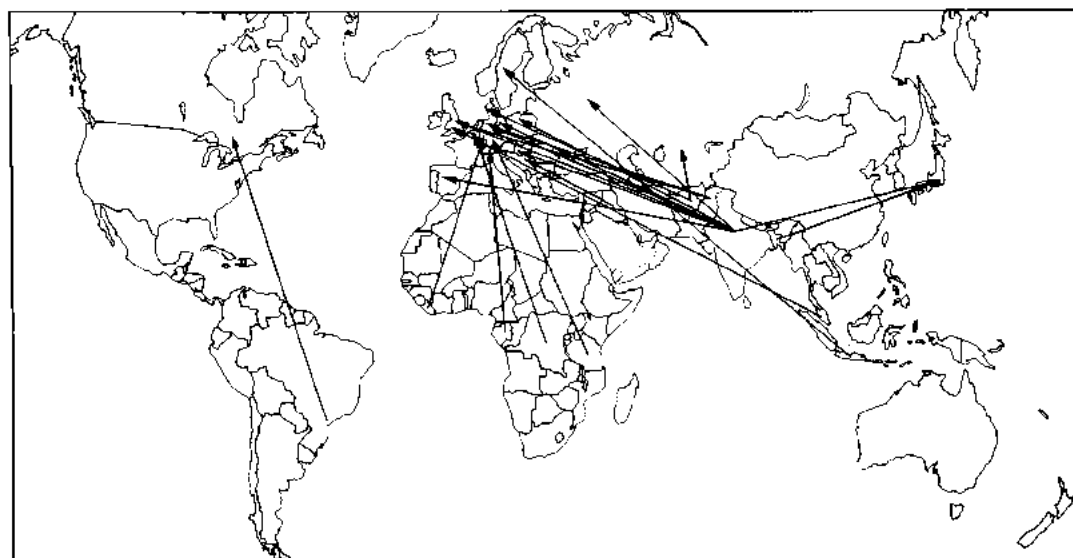

Fig. 23.1. International transfers of smallpox from Africa and Asia to Europe and Japan, 1959-1974, and from Brazil to Canada in 1962. In several cases one arrow represents several transfers, e.g., between India and the Federal Republic of Germany and between Pakistan and the United Kingdom.

which followed an importation into Stockholm, Sweden, in 1963 and caused 27 cases of smallpox and 4 deaths, some 300 000 persons were vaccinated in a period of a few weeks, with 1076 reported complications, of which 77 were serious (Ström & Zetterberg, 1966).

In the late 1960s and 1970s, when surveillance and containment were accepted as the best method of smallpox control, mass vaccination campaigns were rarely undertaken. One exception was the mass vaccination programme undertaken during the large outbreak in Yugoslavia in 1972. Earlier, in 1970, the Federal Republic of Germany had considered mass vaccination when an outbreak occurred at Meschede Hospital, but had been persuaded by WHO not to implement this operation, on the grounds that it was unnecessary and would be costly and likely to result in many complications.

The two countries in Europe with the most importations, the Federal Republic of Germany and the United Kingdom (see Table 23.2), maintained special hospitals for the isolation of smallpox patients, which were held on stand-by in case of a possible outbreak of the disease. The last of these hospitals in the United Kingdom, the Catherine-de-Barnes Isolation Hospital near Birmingham, was not closed until 1985. At the 1976 Winter Olym-

pic Games in Austria, a special building with 8 beds was set aside for use as a smallpox hospital in the event of an outbreak and was identified as such.

Clearly, the health authorities of the industrialized countries remained highly apprehensive of the danger of smallpox, a view shared by the general public. This was evident in the Meschede outbreak, during which motor vehicles bearing a Meschede number-plate sometimes had difficulty in obtaining petrol from garages in other parts of the Federal Republic. As late as 1978, after the laboratory-associated outbreak in Birmingham, England, health authorities in 8 countries demanded valid vaccination certificates for a period of many weeks from all passengers arriving from the United Kingdom, and the authorities in another 6 countries required them from passengers who had been in Birmingham in the previous 14 days.

The attitude to importations in developing countries was not so rigorous, except in those in which a recent campaign had led to the eradication of the disease and thus to a heightened sense of the risk of importation. In the developing countries, many importations resulted in substantial outbreaks and on several occasions to the re-establishment of endemicity.

### Actions Taken by WHO

Although the health authorities of the industrialized countries were responsible for controlling any importations, after the establishment of the Intensified Smallpox Eradication Programme WHO took several steps to assist them. An emergency supply of vaccine was held in Geneva, and the health authorities of all countries were notified that members of the WHO Smallpox Eradication unit were prepared to travel at short notice to any country requesting assistance. This rarely proved necessary, but the Smallpox Eradication unit maintained close telephone contact with the relevant health authorities until the emergency was over. However, Henderson and a WHO consultant, Dr Paul Wehrle, assisted in the investigation of the unusual outbreak at Meschede (see Chapter 4); vaccine and WHO technical assistance were supplied to Yugoslavia in 1972; and in 1978 Dr Joel Breman, then a member of the unit, visited the United Kingdom to take part in the inquiry into the laboratory-associated outbreak in Birmingham.

Assistance was also provided by WHO after importations of smallpox into Bangladesh, Botswana, the Gulf states, and the Sudan. Finally, reports of smallpox in non-endemic countries which reached WHO through the reporting system were always investigated to ascertain whether or not they were due to misdiagnosis or to clerical error. Such investigations had been conducted throughout the programme and even after eradication, during the operation of the international rumour register (see Chapter 28).

The *Weekly epidemiological record* was a very useful means for the prompt dissemination of information about smallpox (see Chapter 10); it was widely distributed by WHO to Member States, particularly to their epidemiologists and port and airport health services. In 1968, a large number of reprints of an article by Dumbell (1968), "Laboratory aids to the control of smallpox in countries where the disease is not endemic", was given special distribution to Member States. Also in 1968, the Smallpox Eradication unit invited Dr Thomas M. Mack, then an epidemiologist at the United States Communicable Disease Center, to WHO Headquarters, where he reviewed importations of smallpox into Europe; his paper, "Smallpox in Europe, 1951-1971" (Mack, 1972), was the first comprehensive analysis of the epidemiological

pattern of smallpox importations into non-endemic countries.

### SMALLPOX IN EUROPE, 1959-1978

Over a period of 20 years, from 1959 to 1978, 13 European countries—about half the larger countries of the continent—reported the occurrence of cases of smallpox. Excluding laboratory-associated outbreaks, which are discussed at the end of this chapter, there were 34 importations from endemic countries, and on 4 occasions the disease spread to neighbouring countries (Table 23.2).

Outbreaks occurred in Europe each year from 1959 to 1973, except 1964, 1966 and 1971, with the largest numbers in 1961, 1962 and 1963. In all, 573 cases were recorded, including the imported (index) cases. The largest outbreaks consisted of 175 cases in Yugoslavia and an associated case in the Federal Republic of Germany (1972), 99 cases in Poland and an associated case in the German Democratic Republic (1963), 47 cases in the United Kingdom (1962), and 46 cases in the USSR (1959-1960). The other 30 introductions caused single-case outbreaks on 14 occasions and outbreaks of 2-33 cases on 16 occasions. Although two-thirds of the outbreaks led to no more than 5 cases, their impact on the communities in which they occurred was out of proportion to the real risk; cases always made the headlines in the newspapers, many persons sought vaccination, and in the larger outbreaks mass vaccination campaigns were urged or undertaken.

The Federal Republic of Germany and the United Kingdom, which together accounted for 19 of the importations from the endemic countries during this period, were the most frequently affected, in part because of the more frequent travel between them and the Indian subcontinent.

### Sources of Importations

Asian countries were the source of infection for 28 of the 34 introductions from outside Europe; in only 5 instances was infection brought from Africa, once each from Gabon, Liberia and the United Republic of Tanzania, and twice from Zaire. The Indian subcontinent was the principal source of importations, 14 coming from India and 8 from Pakistan.

As the smallpox eradication programmes progressed in the endemic countries, introductions of smallpox into Europe became less and less frequent—23 in 1959–1963, 7 in 1964–1968 and 4 in 1969–1973 in spite of the increase in the volume of air travel over this period.

Twenty-seven of the 29 importations from overseas for which data are available were associated with air travel, but none resulted from transmission on an aeroplane; all the infected persons were in the incubation period or the prodromal phase of the disease, when virus was not transmitted. The 2 outbreaks in 1962 in which the index case travelled by ship were recognized during the voyage or when the ship docked, as the patients arrived with fully developed signs

and symptoms. On one occasion only (No. 33 in Table 23.2) was the index case known to have travelled by bus, and the prodromal symptoms of smallpox, which were taken to be due to fatigue from the long journey, did not develop until after the arrival of the person concerned in Yugoslavia.

In 4 instances, cases were imported from one European country into another. A single case that occurred in Schaffhausen in Switzerland in January 1962 was probably infected in Düsseldorf, in the Federal Republic of Germany, at the end of December 1961 (No. 12 in Table 23.2). In 1970, a case in Tromsø in Norway had been exposed to one in Denmark (No. 32), and a case occurred in the Federal Republic of Germany in a man who had been exposed during the epidemic in Yugoslavia in

1972 (No. 33). The large outbreak in Poland in 1963 (No. 22) was probably responsible for a single case in the German Democratic Republic later that year.

### Nature of Index Cases

The index case in importation No. 4 (Table 23.2) was said to have been infected with virus transmitted from Afghanistan on a carpet, but little additional information is available; all other outbreaks were known to be due to the entry of infected persons. Of the other 31 importations into Europe (details are lacking for No. 2 and No. 11), 20 of the index cases occurred in Europeans who had recently visited smallpox-endemic areas. Their occupations varied; among them were 4 physicians and 4 engineers or electricians. Only 11 index cases (7 adults and 4 children) were nationals of an endemic country: 7 were Pakistanis and 4 were Indians and all of them were visiting relatives or friends in the United Kingdom, except for an Indian visiting the Federal Republic of Germany.

Among those importing smallpox, the proportion of males to females was 26 to 5. Twenty-four were adults; the youngest was a 6-month-old baby infected in Zaire (No. 30 in

Table 23.2) and the oldest a Swiss nurse aged 70 years who was infected in Gabon (No. 23).

Only one-third of the index cases gave histories of apparently satisfactory smallpox vaccination. In spite of the availability of potent vaccine and the concern of health officers in European countries regarding importations of smallpox, case histories revealed that most of the Europeans responsible for importations were not well protected when visiting endemic countries. It was estimated that about 70% of the importations resulted from unsatisfactory revaccinations, for which poorly kept liquid vaccine seemed mainly responsible. Throughout the global eradication programme health officials expressed great concern about forged vaccination certificates and focused much of their attention on this matter, but it probably played a fairly marginal role, only a few migrants from the Indian subcontinent being implicated.

Of 28 index cases who arrived from abroad by plane, only 5 had signs of disease on arrival, including an acne-like rash and lesions on the lips. Six arrived in the prodromal, influenza-like stage and the remaining 16 landed apparently healthy; it was impossible to identify any of these cases on arrival. One-third of those who were incubating smallpox

≥ 22	5	339	67.8
Total	30	533	17.7

<sup>a</sup> Interval between the date of onset of fever in the first case and date of notification to the health service.

fell ill within 3 days of their arrival and the other two-thirds by the end of the first or the second week after arrival. Recognition of the disease and its notification were often delayed, since the doctors who saw the cases often did not suspect smallpox and were usually unfamiliar with its clinical picture.

### Delays in Notification

Of 30 importations for which data are available, 21 were recognized as smallpox within 2 weeks of the arrival of the index cases, indicating that the importations were discovered within one incubation period of the first generation of the cases (Table 23.3). On 5 occasions (No. 12, No. 13, No. 21, No. 22 and No. 33 in Table 23.2), delays of more than 3 weeks (range, 22-42 days) occurred before the recognition of smallpox. All these outbreaks resulted in serial transmission for 3 or more generations (see Table 23.4). Clearly, the longer the delay in discovery, the greater was the number of cases that occurred. Sometimes, however, the index case was promptly recognized but a first generation case was missed, as in importation No. 18, in Cardiff, Wales, in which the index case was correctly diagnosed within 4 days of the onset of fever, but a female first-generation patient was not discovered for 20 days; 47 cases occurred in this outbreak, despite early detection of the index case.

### Transmission from Imported Cases

In 14 of the 34 importations into Europe there were no secondary cases (Table 23.4). Of 20 importations in which transmission occurred, 12 resulted in 1 or 2 indigenous generations and 5 in 3 or 4 generations; in

only 3 importations were there more than 5 generations of transmission. Except for the last-mentioned outbreaks, containment measures were successful in interrupting transmission within about 2 months.

### Seasonal effects

Although importations occurred at all times of the year, they were more numerous in the winter and spring (Table 23.5), the usual periods of seasonal increase in smallpox incidence in the endemic areas of the Northern Hemisphere from which most importations originated. The importations at this time of the year usually caused considerably larger outbreaks than those in the summer and autumn, showing that the temperate countries of Europe were also subject to seasonal influences.

### Cases infected in Europe

Of the 573 known cases, 35 were index cases infected outside Europe, including 3 cases on board ship in outbreak No. 19. Of the 537 indigenous cases, 277 (52%) were infected in health establishments or during the course of medical or nursing duties (Table 23.4); 57 (21%) of them were fatal. The other 261 cases resulted from intimate contact with cases in affected households or from casual contacts in institutions such as schools or factories. Although most cases in Europe were cared for in well-equipped hospitals, these institutions played an important role in the further dissemination of smallpox and posed a real risk for other patients as well as staff. The routine vaccination of hospital staff was recommended in Europe and North America, but it was rarely carried out satisfactorily. Most cases occurred among young medical professionals, nearly 20% of whom had never been successfully vaccinated. In contrast, cases among hospital patients and visitors occurred most frequently in young children and aged persons. A few cases were reported in seamen and port employees, as in outbreak No. 19. A Czechoslovak Airlines navigator who contracted smallpox (No. 26) was infected during his stay in Bombay, not on his plane.

### Case-fatality rates

There had been several importations of variola minor into Europe during the first half of the 20th century, but all importations

Table 23.4 Europe: smallpox outbreaks by generation

<sup>a</sup> Infection said to have been transmitted on a carpet.

after 1959 were of variola major. The overall case-fatality rate of 16% (see Table 23.2) was of about the same magnitude as that in endemic countries, the deaths occurring primarily in unvaccinated infants, in persons with contraindications to routine vaccination, and in older patients who had been vaccinated many years earlier.

#### *The extent of individual outbreaks in Europe*

Except for a few outbreaks, smallpox importations into Europe did not produce large numbers of cases, reaching double figures in only 11 outbreaks, even though some outbreaks were not discovered for as long as 3 weeks after the onset of illness in the first case (Table 23.3). Forty per cent of the importations caused no further transmission. After 1963, only 2 outbreaks occurred in which

there were more than 2 cases, and both were associated with unusual circumstances: severe cough and the aerosol spread of virus in outbreak No. 31 (Meschede), and spread in Yugoslavia in one of the country's least developed areas, involving an unrecognized case in a man who was moved from hospital to hospital (No. 33). The fact that there was not greater spread can be attributed in part to the prompt isolation of patients at home or in hospital and to the generally rapid and effective application of control measures.

Especially after 1967, however, smallpox importations into Europe received extensive press, radio and television coverage. Despite the prompt measures usually taken by the public health authorities, the deep-rooted if sometimes unfounded fears of the population were difficult to quell. Several countries suffered considerably in consequence. For

**Plate 23.2.** Some non-endemic countries kept special hospitals ready for the isolation of patients in case smallpox was imported. Sign on a public road in Yorkshire, England, during an outbreak of smallpox in 1953.

example, in the first few days after the recognition of the large outbreak in Yugoslavia, the country was in turmoil: people were afraid to visit public places until they and their families had been protected by vaccination; trucks carrying market products from affected areas were turned back; tourist bookings were cancelled; and some countries closed their borders and advised their nationals not to visit Yugoslavia. Only after a

steady flow of epidemiological information and surveillance data had reassured neighbouring countries were the last of the restrictions on trade and travel dropped, some 12 weeks after the beginning of the outbreak.

### Case Studies of Importations into Europe

Detailed accounts of 2 outbreaks following importations into Europe are given elsewhere: outbreak No. 31 in Chapter 4, as an example of the airborne transmission of smallpox, and outbreak No. 33 later in this chapter, as part of the epidemic that spread across south-western Asia into Europe in 1970–1972.

Two other examples illustrate different aspects of smallpox outbreaks after importations into Europe: an outbreak (No. 16) in Bradford, England, in 1961, in which

**Plate 23.3.** The airborne spread of virus from this 20-year-old electrician, infected in Pakistan, caused smallpox in 17 other patients in the 1970 outbreak in Meschede Hospital, Federal Republic of Germany, described in Chapter 4. He had had no direct contact with any of them.

BY COURTESY OF MESCHEDER HOSPITAL.

transmission occurred in 3 hospitals; and an episode (No. 32) in Denmark and Norway in 1970 that led to only 1 further case despite the original patient's having had numerous contacts.

#### *The Bradford outbreak*

The outbreak in Bradford started with a 9-year-old Pakistani girl, who developed smallpox in December 1961. She had travelled with her family from Karachi to London by air on 16 December 1961, and then by train to Bradford on 17 December (England and Wales, Ministry of Health, 1963). On 5 December, she had been vaccinated against smallpox and issued with an international certificate of vaccination. On 23 December she was admitted to Bradford Children's Hospital with symptoms of malaria, and the presence of *Plasmodium vivax* was confirmed by blood examination. She responded to anti-malarial drugs and was afebrile from 24 to 26 December. On 27 December she developed a low-grade fever and became apathetic and listless. Two days later her temperature rose to 40 °C. On 30 December she developed petechiae on her face and neck and died. A post-mortem examination on 1 January 1962 attributed death to staphylococcal septicaemia and malaria. She was flown to Pakistan to be buried. Smallpox was not suspected; even the physical evidence of recent vaccination was not noted.

Between 11 and 13 January 1962, 10 first-generation cases of smallpox were discovered in the Bradford area (Fig. 23.2) and virologically confirmed. All were unvaccinated before this episode, except case No. 2, in a 40-year-old visitor to an affected ward at Bradford Children's Hospital—a man who had been vaccinated while a member of the armed services during the Second World War—and case No. 3, a resident cook at the Bradford Children's Hospital, who became ill on 6 January. The cook was admitted on 11 January to the Leeds Road Hospital, where a diagnosis of smallpox was made; she died the next day. The other cases were in 6 unvaccinated child inpatients (cases No. 4–No. 9), an 18-year old nurse (case No. 10), and the 37-year-old pathologist (case No. 11) who had performed the post-mortem on the index case; 5 died.

The patients were promptly isolated and vaccinated; only 3 second-generation cases were recognized. The first 2 of these were in

elderly male patients (cases No. 12 and No. 13) in the ward of another hospital (St Luke's) to which case No. 2 had been admitted just prior to his death. The third was a boy (case No. 14) who had been in contact with case No. 6, a child who had been transferred to the Wharfedale Children's Hospital. All 3 second-generation cases were confirmed virologically; 2 recovered and 1 died, apparently from a heart attack.

To sum up, the Bradford outbreak comprised 14 cases; 7 of the patients died, 6 of them from smallpox. All the indigenous infections were contracted in hospital, and 4 hospitals were involved, with transmission in 3 of them. The outbreak was already rather large by the time it was recognized as being caused by smallpox, and there had been numerous opportunities for transmission, both within hospitals and in the general community. The task of identifying, tracing and vaccinating more than 1400 contacts and keeping them under surveillance was expensive, difficult and time-consuming. Although mass vaccination was never contemplated, vaccination clinics were opened because so many people had been already exposed by the time the outbreak was recognized. Practically the whole of the town's population of 250 000 was vaccinated within 5 days (Douglas & Edgar, 1962).

This episode illustrates the unpreparedness of hospitals in the United Kingdom to cope with an outbreak of smallpox at that time, given the large proportion of unvaccinated professional and domestic staff, the difficulty of recognizing haemorrhagic-type smallpox and the risks thereby incurred, and the problems encountered in effectively containing the outbreak once it had been recognized. The response to the provision of vaccination clinics demonstrated the existence of considerable public fear and apprehension about smallpox.

#### *Outbreak in Skodsborg, Denmark, and Tromsø, Norway*

In August 1970 smallpox was imported into Denmark by a 22-year-old Danish medical student who had returned to Copenhagen after a curtailed holiday in Afghanistan. He had been successfully vaccinated in 1956 in Norway and revaccinated with liquid vaccine in May 1970, but the result had not been checked and he said later that the revaccination had been unsuccessful. He arrived in

Fig. 23.2. Outbreak of smallpox in Bradford, England, in December 1961–January 1962. All cases were hospital-associated. The index case was a Pakistani girl who was admitted to the Bradford Children's Hospital and died of unrecognized haemorrhagic smallpox. Cases No. 4–9 were patients at that hospital, case No. 2 a hospital visitor, and cases No. 3, 10, and 11 a resident cook, a nurse and the pathologist, respectively. The three second-generation cases occurred at another hospital to which case No. 2 had been admitted, and case No. 14 at a third hospital to which case No. 4 had been admitted before it was realized that he had smallpox. (Based on England and Wales, Ministry of Health, 1963.)

Kabul early in August, and was admitted to hospital on the 14th, suffering from severe gastroenteritis. Because cholera was suspected, he was transferred to the infectious diseases ward, where he was exposed to cases of smallpox between 17 and 19 August. On 26 August he returned to Copenhagen, feeling reasonably well and with a normal temperature.

On 28 August, when he was living in the staff quarters of the Skodsborg Hospital, near Copenhagen, he became feverish and was treated with penicillin. The next day he developed a rash, which was attributed to the penicillin. On 31 August he was admitted to the infectious diseases ward of the Blegdam Hospital with a diagnosis of pneumonia and dysentery. On 2 September, smallpox was suspected and he was placed in isolation. The State Serum Institute in Copenhagen confirmed the diagnosis by laboratory examination a day later. On 4 September the rash became confluent and haemorrhagic, and secondary infection occurred, with severe

pneumonia. He later developed renal symptoms and died.

Some 400 direct or indirect contacts of the patient were identified, traced, vaccinated and put into quarantine at the Blegdam Hospital. They were mainly persons who had lived with the medical student in the dormitory at the Skodsborg Hospital and personnel at the Blegdam Hospital who had cared for the patient or had had contact with his clothing and bed-linen.

The Danish health authorities at no time contemplated mass vaccination, but maintained an alert for potential secondary cases until mid-October, because there might have been a missed case which would be detected only if the infection were transmitted to others. However, the only subsequent case that did occur was recognized in Norway.

Smallpox infection was carried to Tromsø, in the far north of Norway, by a 25-year-old Norwegian medical student who had been living in the staff quarters of the Skodsborg Hospital in a room next to that of the Danish

student. On 28 August, after they had talked briefly, the Norwegian student had left for Norway, travelling by car with another young Norwegian.

At the beginning of September, when the case in Denmark was confirmed as smallpox, the Norwegian medical student was identified by the Danish national health service as being a close contact. The Norwegian health authorities were notified, and on 4 September he was traced, vaccinated and kept under surveillance. Five days after vaccination he developed an accelerated reaction on the vaccination site. On 5 September, 9 days after contact, he developed low back pain and a rash suggestive of smallpox. Paired sera were sent to Oslo for serological tests, the results of which indicated smallpox. The person who had driven with him from Skodsborg to Norway and 33 other possible contacts were traced, vaccinated and isolated, but no further case occurred. This pattern, with good surveillance and minimal or no secondary spread, occurred in about half of the recognized importations into Europe during the period 1959-1973.

### IMPORTATIONS INTO NORTH AMERICA AFTER 1959

The transmission of smallpox had been interrupted in the USA and its territories in 1949. In that year the last known outbreak, resulting in 8 cases and 1 death, occurred in Texas and was probably due to an importation from Mexico, in which the last case of smallpox occurred in 1951. Reports of smallpox during the 1950s turned out on further investigation to have been cases of chickenpox. In Canada, endemic smallpox was eliminated in 1943, but there were 7 imported cases in 1945 and 1946.

As international air traffic increased in the 1960s and 1970s, and many more people travelled from Canada and the USA to Africa, South America and Asia, in which smallpox was still endemic, there was a constant and increasing risk of importing smallpox into North America. In contrast to Europe, there were no introductions of variola major from the Indian subcontinent into North America, despite the fact that Americans were the most numerous short-term travellers to the subcontinent. For example, Mack (1972) estimated that there were over 3 times as many

travellers to India from the USA as from the Federal Republic of Germany (in 1969, 50 000 Americans compared with 14 000 Germans). However, after 1958, there were 5 importations from India into the Federal Republic of Germany but none into the USA. Only 1 importation of smallpox into North America was reported—a single case of variola minor imported from Brazil into Canada via the USA.

Sixteen years after Canada's last case of smallpox, the disease was brought back to Toronto from Brazil in 1962 by a 15-year-old Canadian boy, who had lived for several years in Paraná State, Brazil. At the end of July 1962 he had been in contact with 4 children who were said to be suffering from chickenpox. On 10 August he and his family left Brazil by air and arrived in New York City on 11 August. Just before his departure from Brazil, the boy had developed fever and malaise which were diagnosed as influenza. On arrival in New York he had presented a smallpox vaccination certificate dated 22 July 1962 (*Wkly epidem. rec.*, 1962), but in fact he had not been vaccinated for approximately 6 years (Best & Davis, 1965).

The family remained in New York for some 6 hours before boarding a train to Toronto. Soon after his arrival there on 12 August, the boy developed a rash, which 2 days later had spread widely over the body, showing a typical centrifugal distribution. He was admitted to hospital in Toronto on 18 August. The clinical diagnosis of smallpox was confirmed on 20 August by the isolation of variola virus. Passengers on the plane on which he had travelled from Brazil to New York were identified, vaccinated and placed under surveillance, as were the members of his family and other known close contacts in Toronto. Persons who had travelled on the train from New York or had had possible contact in the railway stations were requested through the mass media to report for vaccination, and those who did so were also placed under surveillance. No additional cases were reported.

### IMPORTATIONS INTO JAPAN

Japan, the only large industrialized country in eastern Asia, had been free of smallpox since 1951. There were a few imported cases each year until 1955; then, after an absence of smallpox for 18 years, 2 importations oc-

YOMIURI PRESS

**Plate 23.4.** The Japanese government official who was infected in Dhaka in 1973 worked in this conference room of the parliament building in Tokyo while suffering the prodromal symptoms of smallpox, which was diagnosed a few days later. Health officials disinfected the room.

curred, in 1973 and 1974, at a time when the number of travellers from Japan to the Indian subcontinent had increased substantially. The first case was in a 33-year-old Japanese traveller, who had stayed in Dhaka, Bangladesh, from February to mid-March 1973, when Dhaka and its surrounding areas were experiencing an extensive epidemic of smallpox (see Chapter 16). The patient, who was reported to have been vaccinated in mid-January, returned to Tokyo via Bangkok on 18 March, became ill on 23 March and was hospitalized on 26 March. On 31 March he was isolated in the Tokyo Metropolitan Infectious Diseases Hospital and a diagnosis of smallpox was virologically confirmed a day later. Close contacts were identified and placed under surveillance, but no secondary cases occurred (*Wkly epidem. rec.*, 1973a).

The second importation into Japan occurred in January 1974 (*Wkly epidem. rec.*, 1974). The index case was a Japanese Buddhist pilgrim, who was exposed to smallpox while travelling through northern India. He had no record of vaccination in childhood, and the result of his vaccination in Japan on 7 December 1973 was interpreted to be a

"reaction of immunity". He developed symptoms on 22 January 1974, 5 days after his return to Japan. Control measures, initiated on 28 January, when smallpox was suspected, included the isolation of the patient and his family, and the vaccination and surveillance of some 270 persons considered to be close contacts, including 19 pilgrims who had accompanied the patient to India. No secondary cases occurred.

#### IMPORTATIONS INTO RECENTLY ENDEMIC COUNTRIES, 1959-1976

Besides the countries of Europe, North and Central America, Oceania and eastern Asia in which smallpox was not endemic in 1959 (see Chapter 9, Fig. 9.3), there were a number of countries in Africa, South America, south-eastern Asia and south-western Asia in which smallpox had been endemic in the 1950s but had been eliminated during the next decade, and which were thereafter exposed to the risk of importations from neighbouring endemic areas. Importations also occurred across the borders of countries that continued to

harbour foci of endemic smallpox (see, for example, Chapter 15, which discusses importations from India into Nepal).

Data on importations into non-endemic countries of South America are reasonably complete from 1959 onwards, but data from Africa and Asia were very scanty prior to the establishment of the Intensified Smallpox Eradication Programme in 1967. Even after 1967, not much information is available on importations into African countries. Comments on importations into these continents are therefore limited to tabulations of importations from one country into another within each continent, from 1959 for South America, and from 1967 for Africa and Asia. However, a connected series of outbreaks in Iran, Iraq and the Syrian Arab Republic in 1970-1972 will be described in greater detail.

### Africa

By 1958, 13 of the 47 countries of Africa appeared to have become free of endemic

smallpox. In the period 1959-1966, when WHO encouraged the remaining African States to institute national smallpox eradication programmes, 17 countries (5 of them reinfected) are believed to have succeeded in interrupting smallpox transmission (Table 23.6). When the WHO Intensified Smallpox Eradication Programme began in Africa in 1967, smallpox was endemic in 23 countries, and between 1968 and 1976 endemicity was re-established in 3 countries.

Between 1967 and 1976, over 70 importations of smallpox from neighbouring endemic countries into non-endemic countries were reported (Table 23.7). International boundaries in Africa, most of them drawn during the 19th century by the European colonial powers, bore little relationship to ethnic or tribal distribution, so that many of them were crossed and recrossed as frequently as were state or district boundaries in a country such as India. The transfer of smallpox across these boundaries occurred repeatedly, and the figures for importations in the late 1960s, when smallpox was becoming much less common and surveillance was improving, are not complete. It is known that in several instances (indicated by the symbol "+" in Table 23.7) there were more importations than those reported; it is also clear that importations from Ethiopia into neighbouring countries were at least as numerous before 1971 as after that year, when effective surveillance began.

In most cases the disease did not persist long after importation, as, for example, after the numerous transfers from Ethiopia to Djibouti and Somalia between 1971 and 1975. However, importations into the Sudan (1967), Botswana (1971) and Somalia (1976) led to the re-establishment of endemicity in the recipient countries and had a considerable impact on the global eradication programme. In each country, transmission persisted until a full-scale eradication programme had been set up and the local health staff had grasped the concept of surveillance and containment, which enabled them finally to interrupt transmission. Of more than 17 importations into non-endemic countries of western Africa that were recorded after 1966, at least 10 originated in Nigeria. Ethiopia was an even more important source country: all but 7 out of more than 47 importations reported anywhere in Africa between 1971 and 1976 originated there.

Table 23.7 Africa: non-endemic countries experiencing importations, 1967-1976, by region

Country of origin			Importing country and year of importation <sup>a</sup>									
Name	Last endemic	Number of incidents	1967	1968	1969	1970	1971	1972	1973	1974	1975	1976

<sup>a</sup> Numbers in brackets indicate the number of reported cases associated with each importation.

### South America

By 1959 smallpox transmission had been interrupted in Chile, Peru, Uruguay and Venezuela. In the 8-year period from 1959 to 1966 another 5 countries became smallpox-free: Argentina, Bolivia, Colombia, Ecuador and Paraguay. Except in Peru, importations during the period 1959-1970 did not result in large numbers of cases. However, in Peru in 1963, following its introduction from Brazil, variola minor became endemic and remained so until 1966. From 1964 onwards, Brazil was the only known source from which smallpox was exported to other countries in the subcontinent (Table 23.8).

### Southern Asia

Apart from importations into countries of south-eastern Asia that had long been smallpox-free (see Chapter 8), information on importations into the non-endemic non-industrialized countries in Asia is fragmentary before 1967 and still incomplete after that date. What is known can be most effectively discussed in respect of 2 regions: countries adjacent to India, and south-western Asia.

#### *Countries adjacent to India*

Reported importations into non-endemic countries near India during the period 1967-1974 are shown in Table 23.9. The 12 outbreaks fall into 5 groups: importations into Sri Lanka, Afghanistan, Bangladesh, Bhutan and Burma.

Importations into Sri Lanka (outbreaks No. 2 and No. 6) and Afghanistan (3 outbreaks, grouped together as No. 7) were effectively contained. Sri Lanka had been free of endemic smallpox since 1951 and was vigilant in its efforts to maintain that status. The 2 reported cases were contained without local spread, vaccination being carried out on a large scale in Kandy (outbreak No. 2) and Colombo (outbreak No. 6) respectively. Three importations into Afghanistan occurred in 1973, the year after smallpox had been eliminated; they were discovered promptly and the containment methods used during the eradication programme limited spread.

The importation of smallpox into Bangladesh early in 1972, following the return from India of millions of refugees, led to the re-establishment of endemic smallpox and to many thousands of cases. Eradication was not achieved until October 1975.

Table 23.9 Importations of smallpox into non-endemic countries adjacent to India, 1967-1974

Serial number	Year	Importing country	Country of origin	Number of reported cases	Comment
1	1967	Bhutan	India	14	2 outbreaks, originated in markets in Assam.
2	1967	Sri Lanka	India	1	-
3	1968	Burma	East Pakistan	181	Affected 14 villages, over a period of 7 months.
4	1969	Burma	East Pakistan	68	Affected 3 villages, over a period of 2 months.
5	1972	Bangladesh	India	Numerous	Refugees returning from India re-established endemicity in Bangladesh.
6	1972	Sri Lanka	Afghanistan	1	German tourist infected.
7	1973	Afghanistan	Pakistan	25	3 outbreaks of 1, 11, and 13 cases respectively.
8	1973	Bhutan	India	6	Originated in West Bengal.
9	1974	Bhutan	India	3	Originated in Assam.

From an epidemiological standpoint, Bhutan is equivalent to an Indian state, so that it is not surprising that smallpox spread across the border from Assam (outbreaks No. 1, No. 8, and No. 9). Because of the small and sparse population the disease did not persist. In Burma, on the other hand, introductions from Chittagong, East Pakistan (Bangladesh), in 1968 and 1969, shortly after smallpox had been eliminated (outbreaks No. 3 and No. 4), spread without control for several months, because it was very difficult for the health services to operate in the area, in which there were many insurgents.

### *South-western Asia*

This region (Fig. 23.3) consists of Iran (now the Islamic Republic of Iran) and Iraq to the north, Israel, Jordan, Lebanon and the Syrian Arab Republic to the west, and the Arabian peninsula, comprising Democratic Yemen, Saudi Arabia, Yemen, and the 5 Gulf states of Bahrain, Kuwait, Oman, Qatar and the United Arab Emirates. The Arabian Peninsula is mostly desert and the majority of the population is concentrated in a few cities. However, this area was the crossroads of smallpox transmission, since between 1 and 2 million pilgrims came to Mecca by sea, land and air every year, many from the endemic countries of Africa and Asia. Even more important were the numerous migrant workers in the Gulf states, mostly from Pakistan and India.

By 1963, all countries in south-western Asia, except Yemen, appeared to have inter-

rupted smallpox transmission, but frequent importations, particularly from the Indian subcontinent, and deficiencies in the notification of cases to WHO (including the occasional suppression of reports) made it very difficult to know precisely when these countries became non-endemic and to judge the magnitude of outbreaks following importations (Table 23.10). Smallpox was poorly reported, not only because of inadequate health services, but also because of national pride and the fear that the presence of the disease might lead to restrictions on travel or the imposition of an economic embargo by neighbouring countries. In Saudi Arabia, it was believed that reports of the presence of smallpox would inhibit visits by pilgrims. The reliance of some countries in this area on their own capacity to control outbreaks of smallpox occasionally resulted in large numbers of cases and the spread of the disease for up to 2 years. In some of these countries, moreover, clinical and laboratory diagnoses were unreliable, so that the health services could not be certain whether the cases that they recorded were indeed smallpox. They hesitated to request WHO's assistance in improving laboratory diagnosis, because the rendering of such support might lead to international disclosure of the suppression of information about outbreaks.

Between 1967 and 1972, Iran, Iraq, Kuwait, Saudi Arabia, the Syrian Arab Republic, or the United Arab Emirates continued to report cases of imported smallpox every year except 1969. Brief comments on these outbreaks are provided in Table 23.10. The

Table 23.10 Importations of smallpox into non-endemic countries of south-western Asia, 1967-1972

Serial number	Year	Importing country	Country of origin	Number of reported cases	Comment
1	1967	Kuwait	Bangladesh	41	Hospital-associated outbreak (Arita et al., 1970); probably spread to Iran. Probably 3 importations from different dhows (Swinhoe, 1970). No local spread.
2	1967	United Arab Emirates	India	10	
3	1968	United Arab Emirates	India	1	
4	1968	United Arab Emirates	India	1	
5	1970	Iran	Afghanistan	29 (1971) 2 (1972)	Reports suppressed; origin of large epidemic that spread westwards (No. 9 and No. 10), eventually reaching Europe.
6	1970	Saudi Arabia	Bangladesh	12	Pilgrims on ship which was quarantined in harbour. Diagnosed by WHO epidemiologist in Riyadh area; not reported by national authorities.
7	1970	Saudi Arabia	?	2	
8	1970	United Arab Emirates	Pakistan	48	Outbreak lasted until June 1971; greatly underreported.
9	1971	Iraq	Iran	37 (1972)	Extension of No. 5; disease became endemic.
10	1972	Syrian Arab Republic	Iraq	54	Extension of No. 9; hundreds of cases, but outbreak controlled within 4 months.

### Suppression of Information on Quarantinable Diseases

Suppression of the reporting of diseases of international importance has been—and remains—a common practice in many countries, both developing and developed. So far as the countries of south-western Asia are concerned, the failure to report smallpox can be ascribed in part to recent experience with cholera. This disease, which had been absent from the area for many years, was reintroduced in the mid-1960s. Governments were unfamiliar with it, and although the outbreaks were caused by the milder *eltor* biotype, there were many deaths. A variety of measures were introduced to control the spread of cholera, including the imposition of a cordon sanitaire, prohibition of the import of goods and widespread vaccination. These had a serious economic impact, which led some governments to suppress reports of the disease. Against this background, it is not surprising that when smallpox was reintroduced after an absence of many years, governments sometimes responded by not reporting. Suppression of information occurred not only at the central national level, but also often at lower peripheral levels within countries. Smallpox, however, was rather more difficult to conceal than cholera.

WHO actively sought to discourage the suppression of reports of smallpox. Several approaches were used. Endemic countries were encouraged to report fully, and when this led to an apparent increase in the recorded incidence the governments were congratulated on their improved surveillance. As the numbers of smallpox cases declined, WHO encouraged countries to offer a reward for reporting cases to both health personnel and the public, to make it clear that government officials appreciated receiving this information. Finally, when rumours of smallpox in what was thought to be a smallpox-free country were reported by such persons as visitors or foreign officials, governments were asked to institute inquiries.

1970–1972 outbreak, which originated in Afghanistan and spread through 4 countries—Iran, Iraq, the Syrian Arab Republic and Yugoslavia—was of particular interest and importance, because of its extent, the degree of underreporting, and its occurrence at a time when the Intensified Smallpox Eradication Programme was in full swing.

#### THE 1970–1972 OUTBREAK IN SOUTH-WESTERN ASIA AND EUROPE

Iran officially reported 29 cases in 1971 and 2 in 1972; Iraq reported 37 cases and the Syrian Arab Republic 54 cases in 1972 (Table 23.10). However, it was known that the actual numbers of cases were much greater, especially in Iran, and it was feared that the epidemic in these countries would cause a substantial set-back to the global eradication programme.

Epidemic spread began in Iran towards the end of 1970, but reports of cases were suppressed. Iran had eliminated smallpox in 1963 by a well-organized mass vaccination

campaign; one additional outbreak is known to have occurred in Khorramshahr in 1967, but it was not reported. Apart from this experience and the excessive measures recently taken against countries which had reported cholera, the authorities in Iran had also to take into account the forthcoming major celebrations commemorating the 2500th anniversary of the Persian Empire, which they did not wish to jeopardize; the major function was to be held in Persepolis, in Fars Province, on 12 October 1971, and the heads of state and dignitaries from more than 100 countries were to attend it.

However, extensive outbreaks of smallpox could not long go undetected in a large, cosmopolitan country such as Iran. Acting on information received through the United States Center for Disease Control, WHO sent a cable to Iran on 13 January 1971: "Informed presence smallpox cases 46, deaths 8, Tabriz, E. Azerbaijan province ... appreciate any additional information." About a month later Iran cabled that 9 cases had, indeed, occurred, saying that 3 infected Afghans in Mashhad had led to 4 more cases there and 2 in Tabriz.

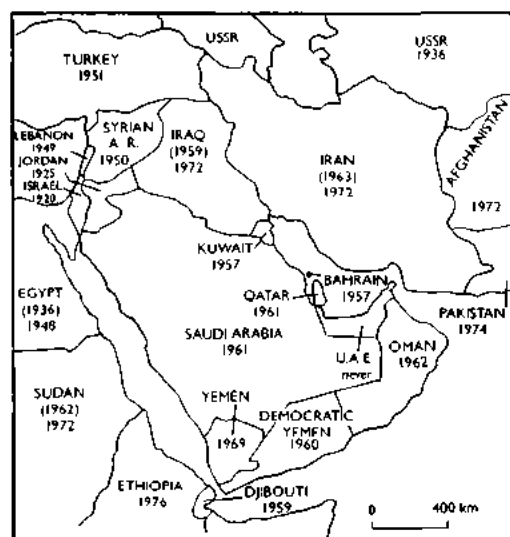

Fig. 23.3. South-western Asia: years in which smallpox ceased to be endemic in each country, before the 1970–1972 epidemic in Iran, Iraq and the Syrian Arab Republic.

No epidemiological details were given and no further cases were reported.

During the following months, reports of smallpox in Iran from various sources grew more and more numerous until finally, on 17 November 1971, the Surgeon General of the United States Public Health Service cabled the following message to the Director-General of WHO: "Reliable reports of smallpox in Shiraz and Abadan, Iran. Can you inquire as to the validity of the report? Until matter resolved U.S. will require valid [vaccination] certificates of arrivals from Iran." It should be noted that the USA had discontinued routine vaccination in 1971 and naturally a smallpox epidemic in a country with which the USA was in close contact was of great concern. Iran's cabled response to an inquiry from WHO, 11 days later, was that 20 cases had occurred between 28 August and 3 October 1971 but none since then, making a total of 29 acknowledged and reported cases in 1971.

Nothing further was heard until 6 March 1972, when Iran, without prompting, notified WHO that 2 cases had occurred on 16 January on its "eastern border". Following a request by WHO for more information, the Ministry of Health stated that the reported cases had occurred in the children of a Baluchi mother who normally lived in Quetta, Pakistan. No information was given as to their

recent whereabouts in Pakistan, and at that time active surveillance had revealed no cases in the Quetta area.

At this point it became clear that an epidemic, which could no longer be concealed, was occurring—and not merely in Iran. On 5 March 1972, Iraq reported to WHO by cable that sporadic cases had occurred on its border with Iran and requested 500 000 doses of vaccine. On 17 March, Yugoslavia reported the presence of smallpox to WHO; on 25 March, the Syrian Arab Republic reported the discovery of 15 cases; and on 28 March, the Federal Republic of Germany notified a case in Hanover, in a man who had come from Yugoslavia. In the face of this evidence, the resistance of all the countries of south-western Asia to reporting the disease weakened, but it did not collapse.

### Iran

Iran (population in 1972, 30.3 million) officially reported 31 cases of smallpox in 1971–1972. The suspicion that there had been many more cases was confirmed following a visit to Iran by Henderson from 2 to 13 August 1972. He reported that over 2000 cases had been hospitalized and that 6000–8000 cases had probably occurred. Subsequently, a confidential government report supplied to the Global Commission for the

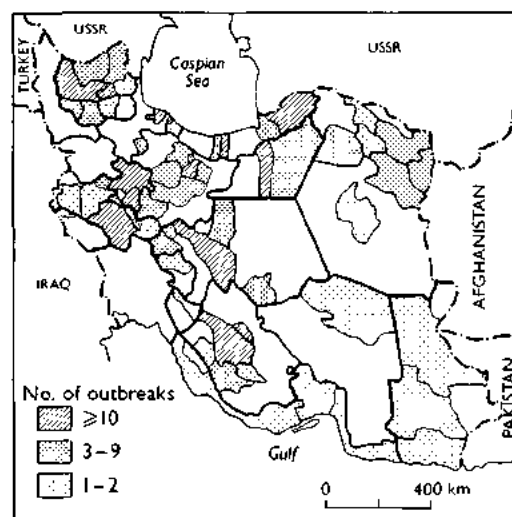

Fig. 23.4. Iran: distribution by district of 400 smallpox outbreaks with some 2000 locally reported cases over the period between November 1970 and September 1972.

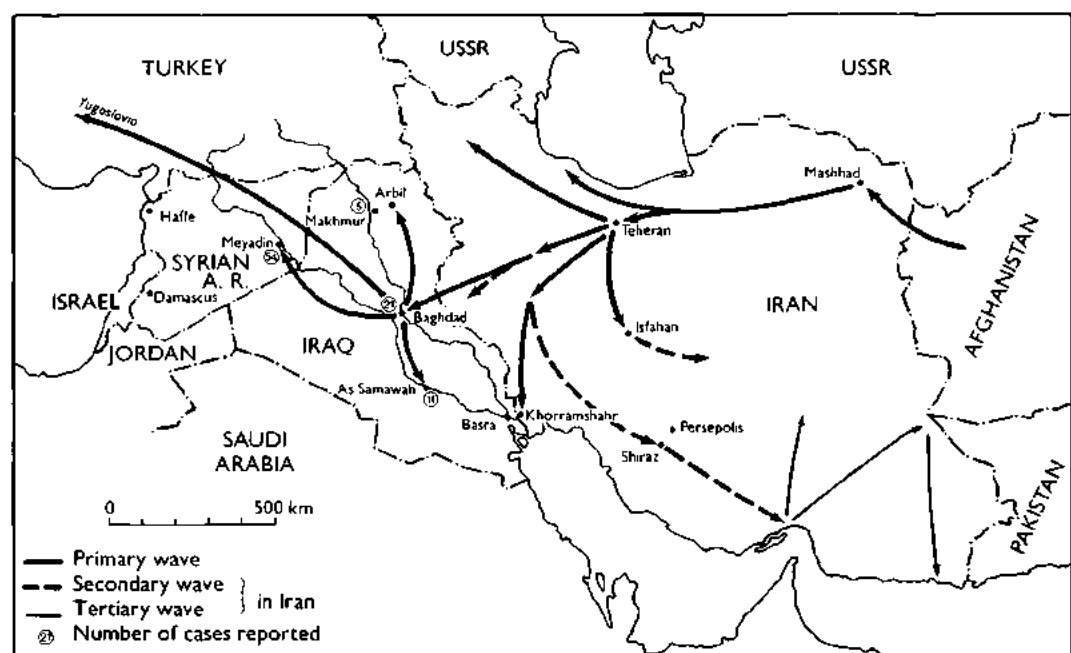

Fig. 23.5. Spread of smallpox in Iran, Iraq and the Syrian Arab Republic, 1970-1972. The disease was introduced from Afghanistan into Mashhad, Iran, in October 1970. There were three waves of dispersion through Iran, which lasted over a period of 22 months. By the end of 1971 smallpox had crossed into Iraq, where it spread north to Arbil and south to As Samawah. Transmission in Iraq was interrupted by June 1972. In February 1972, smallpox spread from Baghdad in Iraq to Meyadin in the Syrian Arab Republic, where a smaller outbreak occurred that was contained by June 1972.

Certification of Smallpox Eradication in December 1978 gave details of 1996 cases in 400 widespread outbreaks between November 1970 and September 1972 (Fig. 23.4). Of these cases, 1349 had been confirmed by laboratory tests.

The epidemic seems to have started when an Afghan family of 6 left their village near Kabul on 16 October 1970 and began a pilgrimage through the smallpox-endemic areas of Afghanistan to the holy city of Mashhad, in Khorasan Province in north-eastern Iran, where several thousand pilgrims congregate daily during the hadj. The family arrived in Mashhad on 20 October. One of the children developed a rash on 3 November and 2 others were similarly afflicted 6 weeks later. Although the first imported case was apparently promptly diagnosed by a local health worker, the disease had already been transmitted to many other pilgrims.

The primary wave of smallpox spread to another 6 provinces in the north (Fig. 23.5), which were to be the most severely affected and for the longest time. Once smallpox reached Teheran it was amplified by hospital-

associated spread, and became a typical urban outbreak affecting slum areas and semi-urban districts around the city. Teheran and the original foci in the northern provinces became the principal sources of infection for another 12 provinces in the west-central part of the country during 1971, from which 2 more in the southern part were affected in 1972. Subsequent review suggested that the confidential report, which had noted that 73% of the cases occurred in cities, seriously underreported the numbers of cases occurring in the rural areas.

The strategy adopted by the health authorities was containment by mass vaccination, with only a rudimentary surveillance component. The little freeze-dried vaccine available was below standard; liquid vaccine was used for most vaccinations. Primary take rates were reported to be no more than 65%. Many persons who claimed to have been vaccinated subsequently developed the disease. Although it was reported that 12.5 million vaccinations had been performed in 1970 and 19.8 million in 1971, smallpox continued to spread throughout Iran. There were major outbreaks

in Shiraz, which was the largest city near Persepolis, where the celebrations were to be staged. The health authorities conducted repeated mass vaccination campaigns in Shiraz itself, but partly because liquid vaccine of low potency was being used, transmission was not interrupted. The authorities were in a quandary; they recognized that the vaccine was of low potency, but could not apply to WHO for potent vaccine because of instructions issued at a higher level of government. Eventually, in November 1971, freeze-dried vaccine was sent to Iran by WHO Headquarters: 2 million doses in 1971, followed by 11 million in 1972. A second round of mass vaccination was performed and during 1972 more than 20.6 million people were vaccinated. The last case of smallpox in Iran was reported from Fars Province, with onset of rash in September 1972.

The epidemic in Iran lasted for 22 months, and at least 400 outbreaks occurred in 70 out of the 162 districts in the country.

### Iraq

Once the Iranian outbreak had begun in Mashhad in November 1970, smallpox moved relatively quickly along the main road to Teheran and Kermanshah, which is the principal route to Baghdad, the capital of Iraq (population in 1972, 10 million). It seems likely that smallpox arrived in Baghdad at the end of 1971 and then spread north and south along the principal roads running parallel to the Tigris and Euphrates rivers (see Fig. 23.5). An estimated 800 cases of smallpox probably occurred in the country, the last case being in Baghdad in June 1972.

The presence of smallpox in Iraq first came to the attention of WHO when a cable was received on 5 March 1972 reporting the presence of smallpox cases on its northern border with Iran and requesting 500 000 doses of vaccine. The Smallpox Eradication unit received further information on the outbreak on 8 March, during the debriefing of Dr N. Maltseva, who had been touring vaccine production facilities in Iraq, Iran and the Syrian Arab Republic in January and February. She reported that there had been cases of smallpox in Baghdad in January. On 18 March, Iraq informed WHO that 20 cases had occurred in widely separated areas: in Arbil in the north-east, in Baghdad, and in As Samawah in the south. A letter dated 19

March from the Ministry of Health mentioned 2 more cases and stated that the infection had spread from Arbil to Baghdad and from there to As Samawah. It was reported that all known cases had been isolated in fever hospitals and that contacts had been vaccinated and placed under strict surveillance. The population of areas in which cases had been notified were subjected to mass vaccination and surveillance measures were instituted. All provinces had been requested to intensify the mass vaccination campaign begun in December 1971. Subsequently, it was reported that over 2.3 million vaccinations were performed in 1971, followed by 8.2 million in 1972 and 1.2 million in 1973.

Three more cases were reported in Baghdad in June and 1 in July 1972. In August Dr Ehsan Shafa, of the Smallpox Eradication unit, visited Iraq. He was presented with records of only 37 cases, with 5 deaths, in 3 provinces, for none of which could the source of infection be determined. However, the pilgrim responsible for the outbreak in Yugoslavia (see below) had been infected between 3 and 6 February 1972, before the onset of any of the reported cases. In addition to Dr Maltseva's report, an oral statement by a WHO nurse indicated that cases had occurred in a province for which data had not been provided. Furthermore, cases from Iraq had given rise to outbreaks in both Yugoslavia and the Syrian Arab Republic, and long experience with smallpox had shown that such exports to other countries usually indicated the presence of an outbreak of considerable size in the exporting country.

When Dr Shafa reviewed the data with a special technical committee in Iraq, the meeting agreed that a number of cases had been "overlooked" or "misdiagnosed". A more realistic estimate put the total number of cases at a minimum of 800. Nevertheless, the measures taken by the health authorities were found to have interrupted transmission in June 1972. Slow transmission might still have been going on undetected only to flare up later, but continued surveillance in the latter part of 1972 and in 1973 indicated that transmission did not continue after June 1972.

### Syrian Arab Republic

On 25 March 1972, the Syrian health authorities notified WHO that cases of smallpox had been discovered in the Syrian

Arab Republic (population in 1972, 6.7 million). The index case was reported to be a 9-year-old boy who had visited Baghdad with his mother for a religious festival between 28 February and 5 March. He developed fever on 9 March, 4 days after his return from Iraq, and rash on 15 March. He was a pupil at the primary school in a village near Meyadin District (see Fig. 23.5). His condition was diagnosed at a dispensary as chickenpox, but on 21 March another schoolchild from the same locality, with a severe skin rash, was diagnosed by a physician in Meyadin as having smallpox. Simultaneously, a physician in another town diagnosed smallpox in 2 other schoolchildren with skin rashes. The disease spread through school contacts to the other villages in the area. A total of 54 cases and 2 deaths were reported, the date of onset of illness in the last case being 27 April 1972.

To control the outbreak, an isolation camp was established in Meyadin and the affected villages were cordoned off. Vaccination of everyone in the Syrian Arab Republic was made compulsory, starting with the affected region. WHO provided more than a million doses of freeze-dried vaccine and a supply of bifurcated needles in March 1972. Health centres and dispensaries were reported to have performed 75 748 vaccinations in 1971, 897 828 in 1972, and 106 176 in 1973.

There were inconsistencies in the data reported. The onset of illness in the index case occurred only a few days before the onset in those reported as secondary cases, an event which suggests multiple introductions or an earlier start to the outbreak. Nevertheless, the government had acted promptly in reporting to WHO and appeared to have done reasonably well in containing further spread.

However, pockmark surveys conducted in 1978 during the preparation of a report for the Global Commission for the Certification of Smallpox Eradication confirmed that far more cases had occurred in the Meyadin area in 1972 than had been reported (see Chapter 26). In fact, one case with pockmarks dating back to 1971 was found in Haffe District, on the other side of the country. Evidence of facial scarring, indicating the occurrence of cases in 1966–1967, which had not been reported, was also found. It was not clear in this instance whether the reporting of cases had been suppressed or whether cases had gone unnotified or had been misdiagnosed as chickenpox. However, the International Commission that visited the country in 1978

found that no smallpox had occurred there after 1972.

### Yugoslavia

The reappearance of smallpox in Yugoslavia in 1972 (population in that year, 20.8 million), after more than 45 years without a case, was totally unexpected and caused great concern throughout the world. The epidemic has been described by Stojkovic et al. (1974) and, more briefly, by Litvinjenko et al. (WHO/SE/73.57).

#### *Origin of the epidemic*

The outbreak began with an infected pilgrim returning from Iraq. A bus-load of 25 Muslims from the semi-autonomous province of Kosovo in the south of Yugoslavia left on a pilgrimage to Mecca and Medina on 1 January 1972. On their way home they spent 3 nights in Baghdad and visited religious sites between Basra and Baghdad from 3 to 6 February, before leaving for Yugoslavia. The index case, a 38-year old Muslim priest, returned to his village of Danjane (population, 750), 20 kilometres north-east of Djakovica (Fig. 23.6), on 15 February 1972. The next day he fell ill with symptoms of fatigue, shivering and fever, which he thought were due to the

Fig. 23.6. Spread of smallpox in Yugoslavia in 1972. The index case arrived from Iraq on 15 February; the last 2 cases in Yugoslavia became ill in Kosovo and Belgrade on 11 April. The case in Hanover, Federal Republic of Germany, occurred on 22 March.

strenuous bus journey of several thousand kilometres. He denied ever having had a rash and a month later no evidence of skin lesions could be seen on his face or body. Although he had been vaccinated on 5 December 1971, no vaccination scar had developed. No one else on the bus contracted smallpox.

#### *Spread of smallpox in Kosovo Province*

A few days after his return, the index case was visited by many of his close relatives, friends and acquaintances, 11 of whom contracted smallpox. Nine cases occurred in Kosovo Province, 1 in Novi Pazar, 160 kilometres to the north (in Serbia), and 1 in a village north of Novi Pazar. These 11 cases were first generation cases, with onsets between 1 and 7 March (Fig. 23.7). None of them was suspected to be smallpox.

It was not until the evening of 14 March that smallpox was recognized by a doctor in the infectious diseases ward of the hospital in Prizren, in the district adjacent to Djakovica, who notified the federal health authorities of suspected smallpox in 4 patients coming from Danjane. The same day 4 other patients admitted to the hospital in Djakovica were recognized as having smallpox.

On 17 March the Yugoslav federal health authorities cabled to WHO that 8 cases of suspected smallpox had been detected. The clinical diagnosis was confirmed by laboratory tests on lesion material at the Institute of Immunology and Virology in Belgrade, confirmation being sent to WHO on 20 March. On 21 March, the WHO Regional Office for Europe informed Member States of the situation and a day later Dr R. Lindner, an Austrian epidemiologist who had previously worked in the Indonesian smallpox eradication programme, was sent to Yugoslavia as a WHO consultant to assist with the investigations.

Between 15 and 31 March, 100 additional cases of smallpox occurred among the immediate family members and relatives of known cases and among the patients of hospitals in Djakovica and Prizren, who had come into contact with cases before the correct diagnosis had been made (Fig. 23.7). This group formed the second generation of cases in Kosovo. Between 1 and 11 April, 14 more cases were recorded in Kosovo. With this third generation of cases the epidemic in Kosovo itself came to an end. It had affected 124 persons, of whom 26 died.

#### *Spread of the disease outside Kosovo*

A tragic and unusual chain of events led to considerable spread outside Kosovo. It started when a 30-year old teacher (Lj. M.), from a village near Novi Pazar, went to Djakovica on 21 February to enrol at the Higher Institute of Education. He came into contact with the index case, became feverish on 3 March after his return and developed a rash on 5 March, when he went to the local medical centre at Novi Pazar and was treated with penicillin. On 7 March he went by bus with his brother to the hospital in Čačak. After spending 8 March in the Dermatology and Venereal Diseases ward in Čačak, he was transferred by ambulance to the Belgrade Dermatology and Venereal Diseases Department on 9 March, because his condition was deteriorating. There he was shown to students and staff as a case demonstrating an unusual drug reaction to penicillin. With the development of severe haemorrhagic complications, the patient was taken, on 10 March, to the Surgical Clinic, where he died during the night. No one in any of the 4 medical establishments through which he had passed had had any suspicion that he might be suffering from smallpox. The brother of the deceased accompanied the body back to Novi Pazar, where it was buried on 12 March. The brother developed a rash on 20 March, and since the Yugoslav medical personnel were by then alerted to the disease, smallpox was diagnosed on 21 March. Only at this point was it realized that Lj. M. had died from haemorrhagic-type smallpox.

Retrospective epidemiological investigation showed that the patient had infected a total of 38 persons, 8 of whom died; 2 were infected in Novi Pazar, 9 in the Čačak hospital (8 patients and a nurse), and 27 in the Belgrade hospitals (20 patients and 7 hospital staff, including 2 physicians and a nurse). In view of the time that had elapsed before the diagnosis was made and of the difficulty of tracing the thousands of contacts of the patient, it was decided to undertake mass vaccination throughout Serbia. A few other cases occurred in additional foci outside Kosovo Province, and 1 case in a Yugoslav migrant worker, who became ill in Hanover, Federal Republic of Germany.

#### *Control measures*

On 15 March, a team of epidemiologists and infectious diseases specialists from Bel-

Fig. 23.7 Yugoslavia: number of cases of smallpox, by date of onset and locality, 1972. The first generation of cases occurred in Kosovo province and adjacent areas; the large second generation in Kosovo, Belgrade and some other places.

grade went to Kosovo and joined local health staff in clinical examinations and epidemiological investigations.

The Province of Kosovo, bordering on Albania, was then a rural, relatively undeveloped area, whose Albanian-speaking inhabitants regarded outsiders with suspicion. The population was composed of large extended families, whose members constantly visited one another, and the men frequently travelled long distances to look for work. Most of the epidemiologists carrying out the field investigations had to communicate through an interpreter with a rather uncooperative population, and this caused them some difficulties. The index case, for instance, never admitted to having had a rash and it was some time before circumstantial epidemiological and serological evidence confirmed the diagnosis of smallpox. The reticence of the man concerned was understandable. He belonged to the semi-secret Bektachi religious sect and was most reluctant to have his illness associated with the pilgrimage or to discredit his religion thereby. Indeed, had he been identified as the source of an infection which had killed several members of his village and of surrounding villages, his life might have been in danger.

Vaccination of the population in the initial foci in Kosovo began on 16 March and was

extended in concentric rings, until by the end of the month almost all the population in the affected province had been vaccinated. There were problems, however, with coverage and unsuccessful vaccination owing to the use of liquid vaccine. It was not until the end of April that 95% successful coverage was achieved. By the third generation of the outbreak, most cases were occurring among persons who had been unsuccessfully vaccinated.

Containment measures in the 25 localities in villages and towns in which cases of smallpox had been detected included the strict isolation of patients, quarantine of their contacts in facilities specially established in hospitals, hotels, pensions etc., and vaccination of the population. In households in which more than one family member had been infected, their home was turned into a quarantine centre. Where necessary, whole villages were put under surveillance, the inhabitants' temperatures were taken and the skin of patients was inspected regularly. Population movement to affected areas was restricted and public meetings were prohibited.

In Kosovo, extensive vaccination of hospital staff and the general population was begun as soon as the diagnosis of smallpox had been confirmed, and the same procedure was

adopted for all 25 smallpox foci. The Federal Epidemiological Commission then decided to undertake a mass vaccination programme throughout the country. In 3 weeks, 18 million out of a total population of 20.8 million were vaccinated.

The epidemic, which caused 175 cases and 35 deaths, was brought under control 6 weeks after the first diagnosis of smallpox. Surveillance for the next 4 weeks having revealed no other case, Yugoslavia was declared free of smallpox on 9 May 1972.

C

**Plate 23.5.** Control measures taken during the 1972 outbreak in Yugoslavia. **A:** More than 300 health teams, some of them army medical units, took part in the vaccination campaign. **B:** Protective clothing worn by medical personnel in emergency smallpox hospitals. **C:** Check-points were established at hundreds of places along the main roads to check vaccination certificates.

It is interesting to note that there was an unusually high proportion of haemorrhagic-type cases: 10% as opposed to the usual 1%. Hospital transmission accounted for 48% of the infections. A high rate of transmission (an average of 12.8 new infections per case) during the second generation of cases was assumed to be associated with inadequate protection from vaccination, 37% of these cases having occurred among previously vaccinated persons. While the number of deaths among previously vaccinated persons was half that among the unvaccinated, the overall case-fatality rate was 20%. The age distribution of cases corresponded with that of the population affected, and the sex ratio was 57% males to 43% females.

The unusual magnitude of the outbreak was considered to be due to the sizeable proportion of susceptible individuals in the population, delayed diagnosis, hospital transmission, the initially large number of unsuccessful revaccinations, communication problems in the tracing of contacts, and an atypical haemorrhagic-type case, which gave rise to the extraordinarily high number of 38 secondary infections.

The spread of smallpox in south-western Asia in 1970-1972 and its importation into Yugoslavia and the Federal Republic of Germany embarrassed several of the countries involved and retarded the progress of the global eradication programme. However, they did help to mobilize support for the programme and to reinforce surveillance efforts in all the countries of south-western Asia.

### LABORATORY-ASSOCIATED OUTBREAKS IN THE UNITED KINGDOM

Microbiological laboratory space inevitably becomes contaminated with the bacteria or viruses in use, the more easily if safety measures are not taken (see Chapter 30). Smallpox laboratories were no exception. However, the regular vaccination and revaccination of persons in any way associated with these laboratories provided good protection against their infection with variola virus.

In countries that still had endemic transmission of smallpox, it was only when cases occurred among laboratory workers that it was possible to ascribe them with any certainty to an infection acquired in a

laboratory. Although laboratory-associated outbreaks of smallpox may have occurred in various countries of the Americas, Asia and Europe when the disease was endemic in them, only 3 known laboratory-associated outbreaks and 1 suspected outbreak have been recognized; they all occurred in the United Kingdom after smallpox had ceased to be endemic there (Table 23.11). Only 2 of these were fully documented: one in London (1973), the other in Birmingham (1978). A single-case outbreak in Liverpool, in 1949, involved a laboratory worker who was accidentally infected with variola virus while handling contaminated materials (A. W. Downie, personal communication, 1980). An outbreak of variola minor in the Midlands and Wales in 1966 was later associated with infection acquired from a laboratory. The 2 confirmed outbreaks will be described first.

### The London Outbreak, 1973

This outbreak followed the last importation of smallpox into the United Kingdom, which occurred in February 1973, when an Anglo-Indian infected during a holiday in Calcutta became ill after his return to London at the end of February (No. 34, Table 23.2). There were no contact infections.

The laboratory-associated outbreak occurred in March and April 1973, during which another 4 cases of smallpox were reported in the United Kingdom (Cox, 1974). On 11 March 1973 a 23-year-old female laboratory assistant in the Mycological Reference Laboratory at the London School of Hygiene and Tropical Medicine became ill with influenza-like symptoms—headache, backache and high fever. She had been

vaccinated as a child and revaccinated in 1972, but did not recall noting any reaction at that time. On 13 March she visited her doctor, who assumed that she had influenza and treated her with oxytetracycline. On 15 March she developed a slight rash and a day later was admitted to St Mary's Hospital, London, with a provisional diagnosis of glandular fever, and placed in a general ward. A drug rash due to oxytetracycline was suspected and later, because she worked in a mycological laboratory, the possibility of fungal infection was considered.

On 22 March she was visited by a friend working in the mycology laboratory, who, at the request of the head of the laboratory, took scrapings from the patient's skin lesions, which were investigated the same afternoon. To the surprise of all, brick-shaped poxvirus particles characteristic of variola virus were seen with the electron microscope. An investigation of the patient's movements before the onset of fever revealed that on 28 February she had entered the poxvirus laboratory (located in the same building as the mycology laboratory) and had watched the chorioallantoic membranes of eggs inoculated with variola virus being harvested on the open bench.

The poxviruses being studied in the laboratory at that time included variola major virus (Harvey strain) and two strains of "whitepox" virus (see Chapter 30). Subsequent investigations showed that it was the Harvey strain of variola virus with which the technician had been infected (Dumbell, 1974).

The patient was taken to Long Reach Isolation Hospital in Dartford, Kent, and the diagnosis of smallpox was confirmed. As many identifiable contacts as possible were traced, vaccinated and placed under surveillance. Unfortunately this group did not include a woman who had occupied the bed next to the laboratory technician's until 20 March, at St Mary's Hospital, nor her son and daughter-in-law, who had often visited her in the general ward. On 30 March the 34-year-old son and his 29-year-old wife fell ill with a headache, back pain and nausea. On 2 April their condition deteriorated and they were admitted to an isolation ward of the West Hendon Hospital with a provisional diagnosis of viral gastroenteritis. A skin rash developed on 3 April and became vesicular a day later, when smallpox was suspected and confirmed by laboratory examination. On the

same day both patients were transferred to the Long Reach Isolation Hospital and died, the wife from haemorrhagic-type smallpox and the husband from confluent ordinary-type smallpox.

On 24 April another case, diagnosed as variola sine eruptione, was notified in a nurse, successfully vaccinated on 4 April, who had tended the couple with smallpox in the West Hendon Hospital. A week later, she had fever accompanied by headache, backache and shivering, with a papular rash on her hands. She was transferred to Long Reach, where a diagnosis was made on the basis of the clinical history.

Thus, the "escape" of variola virus from the London poxvirus laboratory resulted in 4 cases, of which 2 were fatal. The British government set up a committee of inquiry, whose report (Cox, 1974) concluded that the technician had probably been infected by the respiratory route while watching the harvesting of chorioallantoic membranes from eggs on 28 February, and that the other 2 patients had been infected on 17 March, when visiting the hospital.

The important feature of the report, in the light of later actions about methods of handling variola virus in laboratories, is the description of the laboratory facilities used at that time. The report noted that the laboratory was of an old-fashioned design, grossly overcrowded and poorly equipped. Work with variola virus was done on an open bench and a deep-freeze for storing variola virus stood in the corridor. But, as Dr K. R. Dumbell of St Mary's Hospital Medical School testified, the conditions which prevailed there were comparable with those in other teaching hospitals and medical schools in London. Even as recently as 1973, then, scientists working with variola virus did not handle it as a highly dangerous agent but relied on good microbiological techniques and on the regular vaccination of all personnel involved in the laboratories rather than on physical safety facilities. This did not apply to laboratories specially built for handling dangerous microbial pathogens, such as the Microbiological Research Establishment at Porton Down, Wiltshire, in which elaborate physical facilities were provided for the safe handling of dangerous viruses and bacteria. The report concluded with a recommended Code of Practice for Safety in Laboratories Handling Variola Virus (see Chapter 30).

### The Birmingham Outbreak, 1978

Ten months after the last case of endemic smallpox in the world had been detected in Somalia in 1977, the British health authorities reported to WHO that on 27 August 1978, a 40-year-old Englishwoman had been confirmed to be suffering from smallpox. The patient, Mrs Janet Parker, a medical photographer in the Anatomy Department of the Medical School of the University of Birmingham, became ill with fever, headache and muscular pains on 11 August and developed a rash on 15 August. This was at first thought to be a drug rash. She remained at her own home until 21 August, when she was transferred to her parents' house. On 24 August the appearance of vesicles led to a suspicion of smallpox, the patient was admitted to the East Birmingham Hospital and when a diagnosis of smallpox was confirmed by electron microscopy, she was placed in the Catherine-de-Barnes Isolation Hospital. Variola major virus was isolated from vesicle fluid on 27 August. Her condition, complicated by renal involvement, deteriorated rapidly and she died on 11 September.

Mrs Parker had last been vaccinated in 1966. She had not travelled abroad in the

recent past and to the best of her knowledge had had no contact with any persons recently returned from abroad. Indeed, endemic variola major had not been present anywhere in the world since October 1975.

In order to investigate the matter, a Source of Infection Committee composed of 5 experts was established by the University of Birmingham on 28 August 1978. One of the members was Professor Henry S. Bedson, Head of the Department of Medical Microbiology of the Medical School of the University of Birmingham, in which the smallpox laboratory functioned as the regional diagnostic smallpox laboratory. Bedson was an active participant in WHO's coordinated laboratory investigations of variola and "whitepox" viruses (see Chapter 30). The committee suspected that the smallpox laboratory was the probable source of infection.

Meanwhile the health authorities had identified about 290 persons who might have had contact with the patient during her illness. These included the immediate members of her family and other relatives, patients of the East Birmingham Hospital, and colleagues at the Medical School. All were vaccinated and placed under surveillance at

### Impact of the Birmingham Outbreak

In July 1978 there was a growing belief that the last case of smallpox in the world had occurred in Somalia in October 1977. It was not surprising, therefore, that the Birmingham incident led to a great deal of publicity in the media and caused considerable concern in the medical community throughout the world. Health administrators in the developing countries of Africa, in particular, renewed their calls for the cessation of laboratory studies of variola virus and the destruction of all stocks of the virus.

Because of the publicity, WHO received inquiries from the press and from health administrators in many countries concerning proposals for reducing the risk of another escape of variola virus from a laboratory. Information officers were recruited by the Smallpox Eradication unit to handle the inquiries, and Arita, as chief of the unit, developed plans to deal with the situation. Two meetings were convened: a meeting of experts in February 1979 to evaluate the justification for retaining variola virus stocks in laboratories, and a conference in April with the directors of 9 laboratories which were then retaining the virus, together with representatives of the governments concerned, to discuss control measures and future actions.

The plans were debated at a special open meeting held during the sixty-third session of the Executive Board in January 1979, which was attended by a large number of journalists, and the meetings took place as scheduled. Thus the Birmingham laboratory-associated outbreak, though an unfortunate incident, hastened a recognition of the risk of holding variola virus stocks and led to an immediate reduction in the number of laboratories retaining the virus, from 13 in 1978 to 7 in 1979 (see Chapter 30, Table 30.7).

home. Four of them were hospitalized with different illnesses, none of which was smallpox. Three were discharged from hospital, while the fourth person—the 77-year-old father of the deceased patient—developed fever on 1 September, 12 days after his daughter had been brought to his house in his car in the vesicular stage of her illness. He did not develop a rash but died suddenly on 5 September from a heart attack. The tragedy was not over. On 2 September the 49-year-old Professor Bedson was found severely ill after an apparent suicide attempt and died 5 days later. On 7 September Mrs Parker's mother, aged 70, became ill while in quarantine at home and on 8 September developed a sparse macular rash, which was confirmed by laboratory examination as being due to smallpox. She recovered and was discharged from isolation on 22 September.

In view of the mildness of the illness which the second patient developed, as well as the vigorous surveillance and control measures, a further community-wide spread of smallpox was judged to be very unlikely. Priority vaccination was restricted to contacts, persons who worked or lived in nearby foci and persons who needed vaccination to travel.

On 30 August 1978, the Secretary of State for Social Services requested Professor R. A. Shooter to conduct an official investigation, the results of which were published in July 1980 (Shooter, 1980). Dr Joel Breman, from the WHO Smallpox Eradication unit, participated as an observer in the first 3 meetings of this investigation. As in the episode in London in 1973, the index case was in a person not directly connected with work in the smallpox laboratory. Mrs Parker was a medical photographer who worked in another department of the medical school, though in rooms on the floor immediately above the smallpox laboratory (Plate 23.6).

The team of investigators inspected the premises thoroughly, carried out tests on air movement between the laboratory and the photographer's room and made exhaustive inquiries to determine whether there might have been personal contact between Mrs Parker and any worker in the virus laboratory during the last week of July.

It concluded that Mrs Parker had been infected with a strain of smallpox virus used in the smallpox laboratory, probably during the last week of July 1978, but how the virus was transferred to Mrs Parker was less certain.

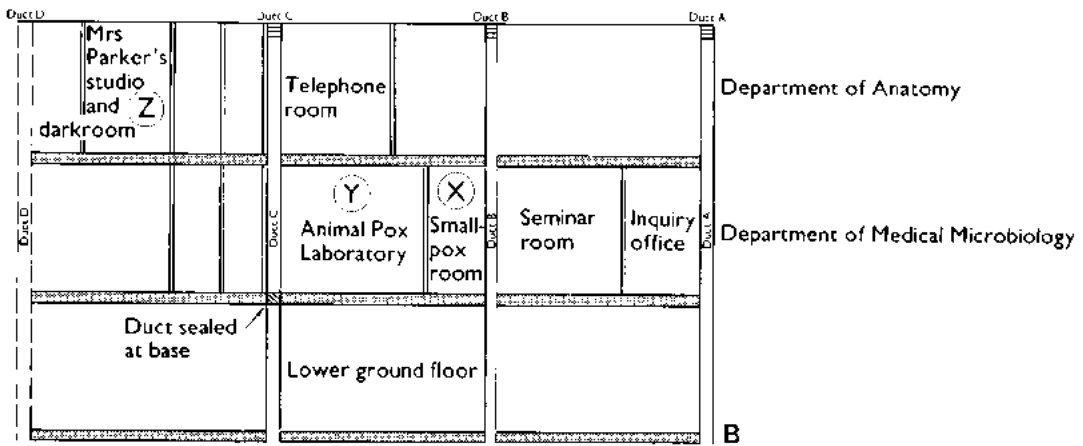

"The evidence points to two possible routes by which smallpox virus was transmitted from the pox laboratory to Mrs. Parker: by the airborne route, either through the duct in the 'telephone room' or while visiting the Medical Microbiology corridor; or by the personal contact route, transfer being by the visitor from the Medical Microbiology Department who regularly entered the animal pox room. We are unable to say with certainty which of these two routes might have led to Mrs. Parker contracting smallpox. Both are possible though neither seems capable of delivering a large dose of virus unless an accident occurred involving the liberation of virus, which was not recognised or recalled. Nevertheless, from what we know small doses of virus could have been liberated from time to time which could have been responsible for Mrs. Parker's infection. We believe that the airborne route through the duct to the 'telephone room' is the most probable way by which Mrs. Parker was infected because this seems to be the one route that could have selectively affected her." (Shooter, 1980.)

This episode constituted the last known outbreak of smallpox in the world, and Mrs Parker's mother the last known case of smallpox in the world. It is ironic that when cases of variola major had occurred again, they had emanated not from a remote source in Africa or Asia, but from a well-equipped laboratory in one of England's largest cities. As a consequence of this episode, much attention was paid to the problem of variola virus stocks in laboratories, a matter which actively interested many Member States at the Thirty-second and Thirty-third World Health Assemblies in 1979 and 1980 respectively (see Chapter 30).

### Outbreak of Variola Minor in the Midlands and Wales, 1966

During the official inquiry into the Birmingham outbreak, the similarity of the apparent origin of an outbreak of variola

X = smallpox room; Y = animal poxvirus laboratory; Z = photographic studio. **B:** Diagram showing location of these rooms and the service ducts running through them. **C:** Photograph of the animal pox laboratory looking towards duct C, which is marked by the letter C. (From Shooter, 1980, with permission from the Controller of Her Majesty's Stationery Office, United Kingdom.)

minor in England and Wales in 1966 was brought to the attention of the team of investigators. The first case in this earlier outbreak to be identified and reported to WHO, on 2 May 1966, was in an unvaccinated 17-year-old girl who had developed an influenza-like illness on 16 April. Four days later a rash appeared, and she was admitted on 25 April to the Moxley Infectious Diseases Hospital, Walsall, Lancashire, as a case of chickenpox. Four days after that, smallpox was suspected and the girl was admitted to a smallpox hospital on 29 April. The diagnosis was confirmed by the isolation of variola minor virus.

Investigation of the girl's family and associates led to the discovery of an additional 71 cases of variola minor in the Midlands and Wales between February and August 1966. Detailed inquiries held in 1966 had failed to establish the source of infection. However, 12 years later, the team of investigators headed by Professor R. A. Shooter carried out a retrospective examination of all available reports and correspondence concerning the 1966 outbreak (Shooter, 1980). The earliest case identified was in an unvaccinated 23-year-old photographer employed at the Medical School of the University of Birmingham. He had become ill on 18 February with fever, headache and backache and had developed a generalized rash 4 days later. During the first week of illness he had remained at home and when the rash had appeared he had returned to work. He denied having had any contact with a person exhibiting a rash similar to his or with any recent immigrants or travellers from abroad. He himself had never been outside the United Kingdom. The relevant feature disclosed during the Shooter investigation was that the photographer had worked in the same studio and darkroom of the Medical School of the University of Birmingham as those used by Mrs Parker.

Eleven days before the index case of the 1966 outbreak became ill, work was being carried out with variola minor virus in the Birmingham smallpox laboratory, on the floor below (see Plate 23.6). Thus the photographer might have been infected, 12 years earlier, by the same route as Mrs Parker; hence the inclusion of this outbreak in Table 23.11 as "suspected" laboratory-associated.

The photographer became ill between 4 and 20 March 1966; his fiancée, his parents and a schoolteacher were infected at a folk-

dance evening, and a 72-year-old man during a visit to a public house. These secondary cases gave rise to 2 main chains of transmission. The first spread from the photographer's fiancée to members of a youth club in her town and from them to their families and associates. The other chain stemmed from the 72-year-old man, who infected 2 of his grandchildren, who in turn infected their friends and families. The spread continued, and at least 25 persons had been infected before 29 April, when the diagnosis of smallpox was made in the 17-year-old girl mentioned earlier. By June, 47 smallpox cases had been reported in the heavily populated West Midlands. Subsequently, new foci of infection appeared in Wales and Lancashire, although no connection could be established between these outbreaks and those in the Midlands, probably because of missed cases wrongly diagnosed as chickenpox.

The last known case occurred in Salford, Lancashire, with onset on 9 July 1966. The patient concerned was discharged from the isolation hospital on 1 August, but in compliance with the International Sanitary Regulations England and Wales were not declared free of smallpox until 18 August of that year. The reaction of the public and the health authorities to this outbreak differed greatly from the response, described earlier, to importations of variola major into European countries. Many cases in the 1966 outbreak had been misdiagnosed as chickenpox, and even when the health authorities became involved, they had not been particularly diligent in searching for cases and isolating and vaccinating contacts. The possible origin of the outbreak was not elucidated until the striking resemblance of the occupation and place of work of the first case to those of the index case in the laboratory-associated outbreak in Birmingham in 1978 became apparent.

## CONCLUSIONS

Smallpox importations into European countries emphasized the risk of infection to which professional staff and patients in hospitals and other medical institutions were exposed. Over half of all cases associated with importations were found in this group, whose protection by regular vaccination with potent vaccine could have reduced the number of cases very substantially. Nevertheless, the

majority of the outbreaks were effectively controlled by surveillance and containment, and smallpox importations caused few disastrous events in Europe.

The review of importations into south-western Asia, especially the epidemic in 1970-1972 that spread from Afghanistan into Iran, Iraq and the Syrian Arab Republic and eventually into Europe, demonstrates that poor surveillance, and especially the deliberate suppression of reports of the disease, had extremely serious consequences both for the countries concerned and for their neighbours.

For most of the period after 1950, the Indian subcontinent was the major source from which smallpox was occasionally transferred to the countries of Europe, especially the United Kingdom and the Federal Republic of Germany, and to non-endemic countries in Asia. The majority of importations into Europe were due to Europeans returning home after travelling in the Indian subcon-

continent. In spite of the large volume of air traffic between the Indian subcontinent and the USA during this period, there were no importations into the latter country, possibly because of the better vaccination status and stricter enforcement of health regulations in the USA than in Europe.

As countries in Africa and South America became free of smallpox, they experienced importations mainly from one country in each of these continents with a large population and extensive endemic foci, which became the major exporter of smallpox to its neighbours—namely, Ethiopia in Africa and Brazil in South America.

The number of diagnosed laboratory-associated outbreaks was remarkably small, probably because of the high level of vaccination among laboratory staff. However, the last tragic incident in Birmingham emphasized the need for close supervision of variola virus stocks during the period following eradication.

## INTRODUCTION

On 8 May 1980 delegates to the Thirty-third World Health Assembly, representing all 155 Member States of the World Health Organization, unanimously accepted the conclusions of the Global Commission for the Certification of Smallpox Eradication (World Health Organization, 1980), namely that:

(1) Smallpox eradication had been achieved throughout the world.

(2) There was no evidence that smallpox would return as an endemic disease.

The first conclusion was based on the findings of a series of independent international assessments, undertaken under WHO's auspices, of the efficacy of smallpox eradication programmes and surveillance in countries throughout the world, especially those in which smallpox had been endemic in 1967 and others at special risk. These activities constituted the programme for the "certification" of smallpox eradication. The second conclusion was founded on epidemiological investigations and research studies carried out during the course of the Intensified Smallpox Eradication Programme and summarized in Chapter 30.

Certification of the eradication of smallpox was possible because the virus had no animal reservoir, subclinical infections were rare and did not result in subsequent transmission, and latent infections did not occur. Just as the strategies and tactics used in the eradication of smallpox in different countries evolved over time (see Chapters 9 and 10), so also did the strategies adopted for certification increase in rigour and sophistication.

The present chapter describes these changing strategies and tactics, culminating with the declaration of global smallpox eradication at the World Health Assembly in 1980. The actual operations involved in the 79 countries in which special measures were taken are described in the following three chapters, which deal in turn with the activities of international commissions for the certification of smallpox eradication between 1973 and 1977 (Chapter 25), the varied activities outlined by the Consultation on the Worldwide Certification of Smallpox Eradication in 1977 and supervised by the Global Commission for the Certification of Smallpox Eradication (Chapter 26), and the final certification operations in the world's last stronghold of smallpox, the Horn of Africa, and in the

world's most heavily populated country, China (Chapter 27).

## HISTORICAL DEVELOPMENT OF THE CONCEPT OF CERTIFICATION

As outlined in Chapter 9, programmes to eradicate specified human diseases from particular localities, and eventually globally, date from the early years of the 20th century. Apart from Jenner's prophetic but hardly practical pronouncement in 1801 (see Chapter 6, Plate 6.8), the first explicit statement about the possible large-scale eradication of a human disease was a comment by Gorgas (1911a) on the eradication of yellow fever, a disease later (1915) nominated for global eradication by the International Health Commission of the Rockefeller Foundation (see Chapter 9). With the realization in the mid-1930s that there was an animal reservoir of the yellow fever virus (Soper, 1936), global eradication of that disease ceased to be a tenable objective. It was replaced by the idea of eradicating its urban vector, *Aedes aegypti*, from countries in the Americas, a concept that gained acceptance in 1942 partly because of the successful eradication of the imported African malaria vector, *Anopheles gambiae*, from Brazil in 1940 (Soper & Wilson, 1943). With these programmes of vector eradication came the need for some means of assessing whether the mosquito in question had indeed been eliminated from particular localities, regions and countries. The first "certification" procedures for *Aedes aegypti* eradication were developed by the Pan American Health Organization in 1954, revised in 1960, and issued in a definitive form in 1971 (Pan American Health Organization, 1971b). The criteria called for the absence of *Aedes aegypti* from a region for a period of at least 1 year, during which 3 surveys confirming the absence of the mosquito had been made. The final survey had to be carried out with the cooperation of the Pan American Health Organization, which provided the technical personnel needed for the task. If the survey confirmed the absence of *Aedes aegypti* mosquitos, the country was entered on the Pan American Health Organization's registry of countries considered free of this species.

When the malaria eradication programme was begun by WHO in 1955, it was realized that some mechanism was needed for convincing those outside the regions and coun-

**Plate 24.1.** Poster produced in the 6 official languages of WHO on the occasion of the certification of the eradication of smallpox from the Horn of Africa on 26 October 1979, exactly 2 years after the world's last case of endemic smallpox occurred in Somalia.

**Plate 24.2.** A complete issue of the WHO magazine *World health* was devoted to smallpox eradication at the time of the Thirty-third World Health Assembly's formal declaration that eradication had been achieved.

tries concerned that they were free of the disease. In 1960, the Thirteenth World Health Assembly requested the Director-General of WHO "to establish an official register listing areas where malaria eradication had been achieved, after inspection and evaluation by a WHO evaluation team". The methodology and procedures for certification were laid down in 1961 (WHO Expert Committee on Malaria, 1961) and amplified in 1966 and 1974. The essential feature of the assessment procedure was that a regional WHO evaluation team would visit the area for which registration had been requested by a government, analyse the epidemiological and operational data collected during the consolidation phase (a period of 3 consecutive years, during which no evidence of transmission had been found and during the last two of which no general measures of anopheline control had been practised), and examine the organization, methodology and quality of the surveillance operations and the plans for their maintenance. Each WHO evaluation team included at least one member of the WHO Expert Committee on Malaria, together with staff from the relevant WHO regional office or short-term consultants appointed by it. National experts from the country being assessed were not included, but the team relied heavily on briefing by them. The team's report was first reviewed at the WHO regional office and later by the WHO Expert Committee on Malaria, and on the latter's recommendation the area was entered in the official register.

With the imminent eradication of smallpox from South America in 1971, it became necessary for WHO, through its Smallpox Eradication unit, to develop procedures for the assessment of the claim that smallpox had been eradicated from the Americas. The earlier eradication programmes had established the important principle that it was not possible for any independent authority, such as a team of WHO experts, acting entirely on its own, completely to confirm the status of a country or region in respect of *Aedes aegypti* or malaria for any definite period of time. Instead, it was necessary for it to depend on records compiled by the national authorities, the quality of which could then be determined by field appraisal undertaken by a team of experts from outside the country.

The global eradication of smallpox, if it could be achieved, would be uniquely different from that of *Aedes aegypti* or malaria since

two valuable but expensive public health measures could then be abolished: routine vaccination of populations in all countries and the requirement that international travellers had to be vaccinated. For this to be possible, however, the world community of public health officials and medical scientists would have to be convinced that global eradication had really been achieved. Assessment of the situation in each country therefore needed to be carried out by teams of highly respected scientists and health officials, independent both of the national authorities of the country being assessed and of WHO, which might be regarded as having a vested interest in the results. Having established the goal of global eradication—never a realistic objective in the case either of *Aedes aegypti* or of malaria—the Smallpox Eradication unit saw that the independence of the assessment teams needed to be placed beyond all possible doubt.

With these requirements in mind, a strategy for the certification of smallpox eradication was developed by the unit. This consisted first of the preparation of detailed "country reports" by the national health authorities of the countries concerned, assisted by WHO staff and consultants. The reports outlined the procedures by which it was believed that smallpox had been eliminated and described the capability of the surveillance system to detect cases of suspected smallpox. When the Smallpox Eradication unit judged that these preparations had reached an appropriate stage, arrangements were made for a group of independent international experts, who constituted what came to be called an "international commission for the certification of smallpox eradication", to visit the country or countries concerned. Their task was to study the country report, make visits wherever they thought necessary, assess carefully the capability of the surveillance system to detect cases of smallpox should they have occurred, and make recommendations about public health activities relevant to smallpox. This was a new strategy designed to solve the novel problem of convincing the international community that smallpox, formerly a universal disease, had been eradicated from particular countries, regions, continents and finally the world. On the basis of experience of the best tactics for particular situations, the certification process was modified and improved, but the essential features—adequate preparations and detailed documentation of the evidence of freedom

from smallpox for at least 2 years, and the independence and authority of the certification team—remained unchanged throughout.

### ERADICATION: DEFINITION AND CRITERIA

To understand the way in which certification of smallpox eradication evolved, it is necessary to examine the definition of, and criteria for, eradication developed in 1967 by the WHO Scientific Group on Smallpox Eradication (1968) and ratified and slightly elaborated in 1971 by the WHO Expert Committee on Smallpox Eradication (1972).

From the time of WHO's foundation in 1948, the control of smallpox had been a matter of concern both to the World Health Assembly and to the WHO Secretariat. The concept of the global eradication of smallpox, as distinct from control within Member States, was first enunciated by WHO in 1958 and accepted as WHO policy by the Twelfth World Health Assembly in 1959 (see Chapter 9). The Intensified Smallpox Eradication Programme was launched in 1967 (see Chapter 10). Between these two dates, 1959 and 1967, the concept of the way in which eradication could be achieved underwent a very important change.

#### Definition in Terms of Vaccination Programmes (1962)

In 1962, in his report on smallpox eradication to the Fifteenth World Health Assembly (document A15/P&B/18; unpublished), the Director-General of WHO defined eradication by stating that: "From a practical viewpoint, countries in which smallpox has recently been persistently present may consider the disease to be eradicated when no cases of smallpox occur during the three years following the end of a satisfactory vaccination programme." In suggesting a period of 3 years, the Director-General was probably influenced by the use of this period in certification procedures for malaria eradication.

#### Definition in Terms of the Interruption of Transmission (1968-1980)

The first meeting of the WHO Expert Committee on Smallpox was held in Geneva

in 1964. The WHO smallpox eradication programme was discussed (WHO Expert Committee on Smallpox, 1964), but no attempt was made to define specific criteria for eradication. However, in 1967 a meeting of the WHO Scientific Group on Smallpox Eradication (1968) specified the basic definition of, and the criteria for, eradication. Meeting in 1971, with 4 years' experience of the Intensified Smallpox Eradication Programme, the WHO Expert Committee on Smallpox Eradication (1972) confirmed both the definition and the criteria, although it stated them in slightly different terms.

The definition produced by the Expert Committee was subsequently endorsed without change by the Consultation on the Worldwide Certification of Smallpox Eradication in 1977 and by successive meetings of the Global Commission for the Certification of Smallpox Eradication in 1978 and 1979. Because they were formulated later, we shall use the 1971 definition of the criteria for eradication (WHO Expert Committee on Smallpox Eradication, 1972) as the basis for discussion:

"Eradication of smallpox is defined as the elimination of clinical illness caused by variola virus. Since smallpox is transferred direct from man to man in a continuing chain of transmission, and since there is no human carrier state of epidemiological importance and no recognized animal reservoir of the disease, the absence of clinically apparent cases in man may be assumed to signify the absence of naturally occurring smallpox.

"In order to be able to confirm the interruption of smallpox transmission an effective surveillance is needed so that clinical infections can be detected. Recent experience indicates that, in all countries with a reasonably effective surveillance programme, residual foci can be detected within 12 months of apparent interruption. Thus, in countries with active surveillance programmes, at least 2 years should have elapsed after the last known case—excluding well-defined and contained importations—before it is considered probable that smallpox transmission has been interrupted.

"Because of the ease with which smallpox can be transmitted from one country to another, the concept of 'eradication' can apply only to a continent. Thus, although smallpox may be considered to have been eradicated from certain continents, it cannot yet be said to have been eradicated from Africa, Asia, or South America.

"On the basis of epidemiological and technical considerations and the considerable experience

acquired so far, the Committee believes that the global eradication of smallpox, as defined above, is possible."

Since the foregoing formulation of "eradication" became the basis of the whole certification process, several aspects of it warrant comment and explanation.

#### *Disease or virus*

In the first paragraph the phrase "Eradication of smallpox is defined as the elimination of clinical illness..." provides the most important criterion; this could be used because, as already pointed out, there was no animal reservoir, subclinical infections were rare and epidemiologically unimportant, and latent infections did not occur. It was therefore logical to base a certification programme on the results of campaigns of active surveillance, which could detect only manifest disease. It would be impossible to use such a criterion for diseases such as plague or tuberculosis.

Furthermore, this criterion took into account the difference between interrupting person-to-person transmission of smallpox and supplementing this by the destruction of all variola virus stocks, as some experts had urged. Achievement of the interruption of human transmission throughout the world was a practical and verifiable goal; ensuring the destruction of all variola virus stocks, in the deep-freeze cabinets of every laboratory in every country of the world, was impracticable and unenforceable.

#### *Period of freedom from smallpox*

In the second paragraph, the stipulation that "... in countries with active surveillance programmes, at least 2 years should have elapsed" before certification could be undertaken, proved to be a conservative but manageable criterion for determining the timing of certification activities, although the choice of a period of 2 years was an arbitrary one. It had been adopted by the 1967 meeting without much discussion, and by 1971 further experience of eradication programmes suggested that it was realistic. In all countries in which WHO-assisted programmes were implemented, the surveillance systems improved greatly during such programmes and, in the great majority of countries, no outbreaks of smallpox had occurred after transmission was thought to have been interrupted. There were, however, a few exceptions. In Brazil,

Indonesia and Nigeria, outbreaks were discovered 10-34 weeks after transmission was thought to have been interrupted, but in no case was the stipulated period of 104 weeks even remotely approached. After these incidents, countries in which national eradication programmes were still in progress further strengthened their surveillance systems. The effectiveness of such systems was always evaluated by WHO before a date was fixed for the visit of an international commission.

In a practical sense, the reliability of certification was related to two factors - namely, the lapse of time since the last known case and the intensity of surveillance. If the intensive surveillance in operation during the eradication campaign had been maintained for 2 years thereafter, this period was more than long enough to judge whether or not eradication of the disease had been achieved. Where longer periods had elapsed, a less sensitive surveillance system was sufficient to detect the serial transmission of smallpox since many hundreds of cases would need to occur to maintain the chains of transmission. Because the supply of susceptible subjects would soon be exhausted, smallpox could not persist for prolonged periods in sparsely populated inaccessible regions; and in towns and cities, in which the population density was high enough to support continued transmission, large numbers of cases could not go unobserved. After eradication had been achieved in the Indian subcontinent, the Smallpox Eradication unit believed that, in countries in which active surveillance had been maintained after an energetic eradication campaign had been successfully completed, the interval could well be reduced from 2 years to 1. However, to make assurance doubly sure, it was decided to adhere to the earlier decision.

#### *Importations and laboratory-associated outbreaks*

The second paragraph of the definition of eradication excludes "well-defined and contained importations". Apart from importations by travellers from endemic countries into countries in which transmission had been interrupted, as occurred in Europe, the Americas, Africa and Asia (see Chapter 23), this exclusion was used by the Global Commission as a basis for its decision regarding the status of the last cases of smallpox in the world. This outbreak, which occurred in

Birmingham, England, in August-September 1978, was associated with variola virus being used for experimental work in the virology laboratory of the University of Birmingham (see Chapter 23). The United Kingdom had been free of endemic smallpox since 1934, although there had been a number of importations from the Indian subcontinent after that date. This event, like the well-contained laboratory-associated outbreak in London in 1973, was regarded in the same manner as an importation into a country that had long been free of endemic smallpox. It was a tragic and potent reminder of the risks of working with variola virus with anything except the strictest containment facilities (see Chapter 30), but it was in no way a threat to the eradication programme.

The outbreaks in China in the mid-1960s, which resulted from the activities of variolators but were not reported to WHO until 1984 (see Chapter 27), could be regarded in the same light as a laboratory-associated outbreak.

#### *Eradication as a "continental" concept*

In the third paragraph, the statement that "the concept of 'eradication' can apply only to a continent" meant that the eradication of smallpox should not be certified when the endemic disease was absent in a single country or even a group of adjacent countries, but only on a continental or global basis. The practice developed of using the terms "interruption of transmission of smallpox" or "elimination of smallpox" to signify the achievement of smallpox-free status by individual countries.

In fact, the certification of eradication in an entire continent was possible only in the Americas. In Asia and Africa it proved impracticable to delay national certification until smallpox was eradicated throughout these continents. Thus in Asia, since there had not been a recorded importation of smallpox into Indonesia since 1949, certification was arranged in 1974, 2 years after the last reported case but before other Asian countries were smallpox-free. Certification of eradication in Africa posed special problems because of the persistence of smallpox in Ethiopia long after freedom from the disease had been achieved in western Africa. Certification activities were therefore not started in western Africa until 1976 and certification in

other areas was undertaken in stages, both because of the shortage of personnel and time and because of the differing eradication programmes of African countries.

### DEVELOPMENT OF STRATEGIES FOR CERTIFICATION

The occurrence of what was believed to be the last case of smallpox in Brazil (and thus in the Americas) in April 1971 forced the Smallpox Eradication unit to plan immediately the steps to be taken before eradication of smallpox from the Americas (in practice from South America) could be certified for acceptance by the international community, in 1973, 2 years after the last case. Two operations new to the unit needed to be planned and implemented: (1) the collection in South America of basic data for the assessment of the smallpox status of each country; and (2) the selection and mode of operation of the international assessment team, which in 1973 would examine the evidence collected during the preceding 2 years. The way in which these operations developed can best be appreciated by a consideration of certification procedures in 3 areas of the world—South America, Indonesia and western Africa.

#### South America

##### *National preparations*

In 1971 a general plan of work was outlined by agreement between WHO Headquarters and the Regional Office for the Americas. It called for specific reports on the smallpox status of all countries in South America except Chile, which, because of its geographical isolation, was judged to be at only slight risk of importations from Brazil or elsewhere, following its last case in 1954. WHO staff and consultants were assigned to visit the various countries, for most of which little information had previously been available, and were instructed to prepare detailed reports in line with requirements specified prior to their visits. While these assessments were being made, it became apparent that the surveillance systems in some of the countries were improving, and the data gathered became increasingly valuable as time progressed. Special programmes were undertaken for the

areas of greatest concern—e.g., the Amazon basin.

Because of the paucity of established health units in the Amazon basin and the inaccessibility of many of the areas of interest, special investigations were undertaken in parts of the basin within Bolivia, Colombia, Ecuador, Peru and Venezuela. The Brazilian parts of the basin were systematically and thoroughly searched by smallpox teams working with the malaria service; these teams progressed systematically through the entire area, vaccinating people wherever they were found and inquiring about smallpox. Other measures, outlined in Chapter 25, were also taken. Because only variola minor had been present in South America in recent decades, pockmark surveys would have been of little assistance, and none was attempted.

#### *A mechanism of international assessment*

Drawing primarily on the precedent of assessment of the malaria status of countries in which that disease was thought to be eradicated, the Smallpox Eradication unit proposed that the results of the reports provided by national authorities and WHO consultants should be evaluated by what came to be called an "International Commission for the Certification of Smallpox Eradication". The first such commission to be established, that for South America, suffered from defects in both its composition and its performance, which were largely remedied when the next one (for Indonesia) was set up and did not recur. In the first place, the Commission for South America included several persons who had been involved in the eradication programme in South America including as chairman, at the insistence of the Brazilian government, Dr Alfredo Bica, Secretary of Public Health of Brazil and formerly Director of the Communicable Diseases Division of the Pan American Sanitary Bureau/WHO Regional Office for the Americas. The Smallpox Eradication unit, for its part, failed to provide a detailed plan of action for the Commission. As a consequence, procedures and records and the history of smallpox eradication programmes in various countries were examined in a rather cursory and superficial manner. Finally, when the Commission framed its recommendations, it showed little appreciation of the significance of the eradication of smallpox from the Americas, calling for continued routine vaccination throughout

the continent, as before. Fortunately for the reputation of the Commission, the Smallpox Eradication unit and WHO as a whole, subsequent history showed that smallpox had indeed been eradicated from South America.

### **Indonesia**

The last case of smallpox in Indonesia occurred on 23 January 1972. Since there was no record of a case of smallpox having been introduced from the nearby endemic countries in Asia since 1949, it was judged appropriate to proceed with arrangements to certify eradication in Indonesia (as an isolated country) in 1974. In the light of the experience in South America, the methods of preparation for certification and for field activities by the members of the International Commission were strengthened.

#### *National preparations*

Like many other governments, that of Indonesia was not enthusiastic about continuing active surveillance after it was believed that smallpox had been eliminated and had to be persuaded of its importance. Then, sufficient data would need to be collected to satisfy the Commission that smallpox had been eradicated. Dr Paul Wehrle, an experienced smallpox consultant, therefore visited Indonesia in order both to identify weaknesses in the surveillance system, and to work with the government and WHO advisers to develop a plan which in his opinion would provide such data. Subsequently, health staff carried out intensive precertification activities, including an active search in high-risk areas and the collection of separate written declarations by the chiefs of tens of thousands of villages, stating that they had searched for smallpox throughout the area under their authority and had failed to find any cases.

Two factors which facilitated the preparations in Indonesia, compared with those in South America, were that pockmark surveys were useful because the prevailing variety of smallpox had been variola major, and that a reward was offered to anyone reporting a case of smallpox.

#### *Selection of members of the International Commission*

Profiting from the experience in South America, the Smallpox Eradication unit

modified the procedure for the selection of members of the International Commission, adopting an approach that was applied in the formation of all subsequent commissions. The major problem with the constitution of the South American Commission was that a national of the major country under examination, Brazil, was appointed chairman. This mistake was never repeated, but after a good deal of debate Dr Julie Sulianti Saroso, Director-General for the Control and Prevention of Communicable Diseases in the Indonesian Ministry of Health, was made a member of the Indonesian Commission. Subsequently nationals of the country concerned were appointed to an international commission only in special circumstances—as in India, where this was necessary to enable the Commission to have access to Bhutan. Governments of neighbouring countries (Australia and Malaysia) were asked to nominate representatives, on the grounds that these countries were most at risk of importations should smallpox still be present in Indonesia so their nationals might be expected to be especially critical of the material presented. In general, the Smallpox Eradication unit took the view that the certification process would be best served by the appointment to each commission of individuals (whether from governments or universities) respected by their own governments so that their opinions on smallpox eradication would also be respected. Great care was exercised in the appointment of the chairman, and the precedent set in Indonesia, whereby Dr Wehrle visited the country during the preparatory period and subsequently acted as chairman of the International Commission, was followed in other countries in which certification was of great importance—e.g., Ethiopia and India. After eradication had been certified in Indonesia, the Smallpox Eradication unit tried to include in each new international commission one or two members who had already had experience with an earlier commission.

This Commission and all subsequent commissions were asked to reach one of two conclusions: either that they were satisfied that eradication had been achieved, or that they would be satisfied that eradication had been achieved if certain specific measures were undertaken. At the initial briefing session in Jakarta, the Australian and Malaysian members of the Commission were extremely doubtful whether eradication had been achieved in Indonesia. One observed

that he had recently heard rumours of cases in northern Sumatra and the other believed that cases were almost certainly occurring in the slum areas of Jakarta itself. Such scepticism was welcomed by the Smallpox Eradication unit since, if these members were persuaded by the evidence presented in the course of the activities undertaken by the Commission itself, their conclusions would be more convincing to the international community.

A feature of the work of the Indonesian Commission was that Dr Sulianti Saroso, speaking as Director-General for the Control and Prevention of Communicable Diseases in the Indonesian Ministry of Health, concluded her opening remarks at the first session by saying that Indonesia was convinced that it was free of smallpox. Consequently, she invited members of the Commission to feel free to "go anywhere, with anyone, and make any inquiries" they chose to. This statement was honoured and provided an important precedent for other international commissions.

### Western Africa

The last case of smallpox in western Africa occurred in Nigeria in May 1970 and United States bilateral assistance was terminated in 1972. At that time, however, smallpox was still endemic in many other parts of Africa and certification was therefore postponed. Smallpox was progressively eliminated from one African country after another, but the stipulation that eradication was a continental concept made the Smallpox Eradication unit reluctant to undertake certification in Africa. However, by 1975 endemic smallpox appeared to be limited to the Horn of Africa, and it was decided to initiate the certification process in the African continent in phased groups of countries so as to reduce logistic and administrative problems. The epidemiological situation in different parts of the African continent was nevertheless borne in mind. A group of 15 countries in western Africa was certified first because transmission had first been interrupted there and because they were furthest away from the areas in which smallpox was still endemic. Surveillance had been intensive in these countries for 2 years after the presumed elimination of smallpox, but had then very largely declined. Documentation on activities carried out since 1972 was comparatively sparse in most countries in the region. On the other hand, the long period of

time that had elapsed since smallpox had been seen in any country of western Africa provided good grounds for believing that the disease had been eliminated and had not been reintroduced. While notification systems were not as well developed as might have been desired, they had been capable of detecting cases of monkeypox in human beings in 1970 and succeeding years, as well as outbreaks of unusual and extremely serious diseases, such as Lassa fever or Ebola virus disease, which had come to the notice of local health staff within 6 months and of central health personnel within 12 months of their occurrence. If smallpox, especially variola major, had occurred in western Africa after 1970, it seemed reasonable to expect that the health staff of the country concerned would have known about it within a year. The 6-year interval since the last case thus provided a very large safety margin.

Because the Commission's visit took place so long after the last known case, many national smallpox eradication staff, as well as United States epidemiologists who had worked in the programme, had long since left and taken up other employment. Moreover, the Commission had to deal with 15 countries covering a vast area—almost two-thirds of the size of the USA—in which the health services infrastructure was much less well developed than in South America or Indonesia. To cope with this situation, WHO regional staff and consultants made frequent visits to these countries and two important changes were made in the procedure. First, preparations for certification were simplified, compared with the elaborate precertification searches and detailed documentation that were used in Indonesia and subsequently in the Indian subcontinent. Preparation of the country reports was based on a standardized questionnaire developed by the Smallpox Eradication unit; when completed, this provided essential information about the national eradication campaign. Secondly, a new method of active search was developed for use in all areas in which variola major had occurred—namely, large-scale facial pockmark surveys in children (see later in this chapter). It was reasoned that, if these surveys included all children up to 15 years of age, there would be some who had had smallpox when it was still endemic and would have pockmarks which the teams should detect. This served as an internal control in the survey, in that failure to detect any individ-

uals with pockmarks would call into question the work of the team concerned. When children with pockmarks were detected, efforts were made to find out in which year they had contracted the disease that had caused the scarring. Such information was surprisingly easily obtained from most villagers. The age of the youngest pockmarked child also provided objective evidence as to when smallpox had last occurred.

Western Africa was certified to be free of smallpox on 15 April 1976, and in May 1976 the Twenty-ninth World Health Assembly, commenting for the first time on the certification process, endorsed "the procedures developed by the Director-General in the use of groups of international experts in the certification of eradication and [asked] for the full cooperation of all countries concerned in carrying out these procedures, so that countries throughout the world may have confidence that eradication has been achieved" (resolution WHA29.54). The successful carrying out of certification in western Africa provided the experience necessary for the staff of WHO and various national health authorities to proceed with certification in other areas of Africa as well as in south-western Asia.

### Coordination of Certification Activities

In consultation with staff from the appropriate regional office and the national smallpox eradication programme, the Smallpox Eradication unit was responsible for deciding whether a particular country was ready to receive an international commission and, if so, when. This obviously required frequent visits by WHO smallpox eradication staff and, on occasion, by WHO consultants, to countries preparing for certification. Thus, even though smallpox had been eliminated from all countries except Somalia by the end of 1976, a number of WHO smallpox eradication staff were retained or recruited to assist in the certification process. From 1977 onwards, the Smallpox Eradication unit in Geneva consisted of Arita, who replaced Henderson after his departure in February 1977, Dr Joel G. Breman, an epidemiologist from the Center for Disease Control, Atlanta, USA, with extensive experience in smallpox and tropical diseases, Dr Alexander Gromyko, Dr James Tulloch and Mr John Wickett. Dr Celal Algan, Dr Ziaul Islam, Ježek, Dr Daniel Tarantola and Dr Lev Khodakevich assisted

the programme as WHO staff members in the regional offices.

Certification of smallpox eradication was not solely a technical matter but also involved many managerial and political questions. Ladnyi, who had acted as WHO intercountry smallpox adviser in eastern Africa from 1965 to 1971, returned to WHO Headquarters in 1976 as an Assistant Director-General and remained in this post until 1983. In this capacity he was able to help to solve some of the political problems that inevitably arose during the organization of certification activities.

The support provided by WHO staff and consultants was of two types. First, in a country in which an eradication campaign had been developed and executed with the active participation of WHO staff epidemiologists or consultants, some international personnel continued to work with national staff after eradication in organizing and assessing the active searches for unreported cases of smallpox, as well as in pockmark surveys or in the surveillance of chickenpox cases. The last-named activity was carried out in a number of countries, being of special importance where variola minor had been endemic, since this disease rarely left pockmarks and was readily confused with chickenpox. Secondly, in countries of western, central and southern Africa, in which the eradication campaign had been organized many years before certification and in which WHO or outside epidemiologists were not involved in continued surveillance, special arrangements were made to assign experienced WHO consultants or staff epidemiologists from either inside or outside the country to assist the health services in precertification activities.

In countries from which smallpox had recently been eradicated great interest was shown in certification, whereas in those in which the disease had been eliminated many years before, certification was not considered by the national health administrators to be of high priority. In some countries, national health officials who had taken part in the national smallpox eradication campaign had risen in the local health service hierarchy and were important in persuading senior government administrators of the importance of certification. The assignment of special WHO consultants and epidemiologists also helped to promote certification activities.

To persuade governments to mobilize adequate numbers of staff to prepare properly for

J. KUMAZAWA, 1980

**Plate 24.3.** Joel G. Breman (b. 1936) was a medical officer with the WHO Smallpox Eradication unit, 1977–1980, during the most active part of the certification programme, and participated in monkeypox surveys in western and central Africa. He also worked as an epidemiologist in the eradication campaign in western Africa, 1967–1969.

certification, several approaches were used: (1) WHO regional office and Headquarters staff communicated with countries by letter or memorandum, emphasizing the importance of certification if the final achievement of smallpox eradication was to be accepted by the world community; (2) further encouragement was provided through coordination meetings with representatives of the countries concerned and through visits by staff of the Smallpox Eradication unit; and (3) WHO funds were frequently provided to cover fuel and vehicle repair costs and the living expenses of national surveillance teams.

### NATIONAL PREPARATIONS FOR CERTIFICATION

The methodologies employed in national preparations for certification (precertification activities) differed according to the variety of smallpox present in the countries concerned and whether eradication was followed immediately by post-eradication surveillance and preparation for certification, or precertification activities were carried out many years after the occurrence of the last known case of smallpox. In most cases the final product was a "country report" that was

assessed by the appropriate international commission or the Global Commission.

The WHO Scientific Group on Smallpox Eradication (1968) had pointed out the need for an effective surveillance system capable of detecting and investigating suspected smallpox cases in order to demonstrate that smallpox transmission had been interrupted. Although all countries in which smallpox had been endemic continued some form of smallpox surveillance after the date of onset of what they considered to be the last case, its intensity differed substantially from country to country. In the last countries to be affected by smallpox, such as Bangladesh, Ethiopia, India and Somalia, the national programmes continued active post-eradication surveillance that was even more intensive than during the eradication campaign itself. The documentation in such countries was more complete than that available elsewhere and these countries could be visited by international commissions just 2 years after they had reported their last case. On the other hand, in most countries of Africa, special surveillance programmes had ceased long before certification was undertaken. In all cases, country reports covered the following items, which are described more fully later:

(1) a description of the routine reporting system;

(2) an account of special active searches, both in high-risk areas and throughout the country, including the methods of assessing the quality of the searches;

(3) the results of pockmark surveys, if appropriate;

(4) a description of chickenpox surveillance, wherever it was undertaken;

(5) the status of rumour registers, in which all suspected cases of smallpox were recorded, and sometimes also cases with fever and rash;

(6) a list of specimens sent for laboratory investigation and the test results;

(7) an account of the publicity given to the need for reporting smallpox cases, the rewards offered for finding a case (where appropriate), and public awareness of such rewards;

(8) documentation on other precertification activities.

### **Effectiveness of the Routine Reporting System**

Each country provided data on the number and distribution of health units, including the

number and types of hospitals, health centres or stations and peripheral health units, with maps showing their distribution throughout the country, and on the regularity and completeness with which they reported. The number of monthly or other periodic reports called for was compared with the number actually received. Data were also supplied on the reporting of cases of chickenpox, especially those with a fatal outcome. Finally, records of the action taken when a suspected smallpox case was reported were examined. During visits by WHO consultants in preparation for certification, action was taken to increase awareness among health personnel of the need to report immediately any cases where smallpox was suspected.

### **Active Searches for Unreported Cases**

In most countries, specially organized mobile teams conducted field surveys in order to obtain up-to-date information regarding activities in connection with smallpox. The teams were organized and directed by the national smallpox eradication programme (when still operative), by those who had been involved in the eradication programme during its active phase, or by those responsible for the communicable diseases programme.

Special investigations were carried out in localities in which the risk of unreported smallpox was thought to be greatest. These included areas in which the last known outbreaks had been notified, those in which suspected smallpox cases or chickenpox deaths had been reported after the last known outbreak of smallpox, and those in which health coverage and communications were poor. Areas bordering on countries in which smallpox had recently been endemic, or in which there had been recent extensive population movements, were also included. Special attention was given to the villages in which the last known cases had occurred. Such investigations provided information as to the effectiveness of control measures and case detection during the concluding phase of the programme in the country. If it was found that all cases in an outbreak had been detected and containment was satisfactory, this increased confidence in the efficacy of the surveillance-containment activities.

A general survey was usually planned for cities, towns, and larger villages, since experience had shown that, if smallpox had per-

### The Absence of Evidence is not Evidence of Absence

From the beginning of the global eradication programme, steps were taken to encourage the submission of all reports of smallpox in any country thought to be free of the disease and to investigate all such reports. There had always been serious doubts with smallpox, as with cholera, whether the absence of reported cases really meant that the disease was absent from the country concerned. Reports of suspected cases of smallpox in non-endemic countries had been queried by the Smallpox Eradication unit since the Intensified Smallpox Eradication Programme began, in order to determine definitely whether or not they were imported cases or whether they represented continuing endemic transmission. As the campaign progressed, such reports took on a greater significance and eventually in 1978 an international rumour register was established in Geneva (see Chapter 28). Rumours were very important. Thus, although no cases were officially reported from Iran after 1963, information that smallpox might be occurring there in 1971 was drawn to the attention of WHO by a WHO consultant as well as by a number of international staff working with other health agencies. Reports of imported cases in Somalia before 1976 were also received from embassies long before being notified officially by the government. Similarly, the serious outbreaks which occurred in the Salt Lake refugee camp in West Bengal in 1971 were unknown to the government and to WHO until reported by an American epidemiologist who had observed cases of smallpox in a television news film taken at the camp (see Chapter 15).

sisted in smaller villages or nomadic groups, it would ultimately reach the larger population centres. The localities to be visited were selected so as to include communities with health units and primary schools, since these attracted people from a large area who might report suspected cases. The usual objective was to reach a sufficient number of communities to ensure that at least 20–25% of the entire population of the country was covered by the survey.

In the countries which were the last to become free of smallpox—Bangladesh, Ethiopia, India, Nepal, Pakistan and Somalia—country-wide house-to-house searches to discover possible cases were conducted on several occasions. A large number of health staff, volunteers and temporarily recruited searchers were deployed so that the search could be completed within a period of 3–4 weeks.

Search teams were organized in order to obtain information about cases of smallpox and chickenpox, actual or rumoured, in primary schools, health units, markets and other places at which people congregated, from nomadic and other migratory groups, and on some occasions from all households in selected villages or urban areas. Their training covered the following aspects:

- (1) The status of smallpox eradication in the country, including details of the last outbreaks, suspected cases, and deaths from chickenpox, and an indication of particular localities requiring special investigations and field surveys.

- (2) The characteristic features whereby facial pockmarks caused by smallpox could be distinguished from scars caused by other conditions. In this connection, it was emphasized that only persons with facial pockmarks caused by smallpox or suspected smallpox were to be investigated and the findings documented.

- (3) Techniques for the epidemiological investigation of suspected cases, including the collection of specimens for laboratory investigation.

- (4) Methods to be used in selecting the itinerary for field visits and the recording and reporting of data.

The organization of active searches in various countries is described in detail in subsequent chapters. One universal and important feature on which WHO consultants and staff preparing for certification insisted, however, was that the effectiveness of the searchers themselves should be properly assessed by follow-up staff whose task was to

**Plate 24.4.** Facial pockmarks. **A:** Moderately severe in a Nigerian girl 7 years after an attack of smallpox. **B:** Severe, in an Afghan who had suffered from smallpox many years before.

evaluate the work done by visiting houses and villages selected at random from among those previously visited by the search teams. Special assessment teams directed by national programme staff were organized for this purpose and each month visited up to 10% of the places previously visited in the course of the searches.

### Pockmark Surveys

Permanent facial pockmarks were found in about 70% of those who survived Asian variola major, the rates being slightly lower after infection with the somewhat less virulent forms of variola major virus found in some parts of Africa. Heavy diffuse facial scarring, readily observed at a distance of 5 metres, was seen on the faces of many victims, but others had lesser degrees of scarring that could be detected only by close inspection. Residual pockmarks, which tended to flatten out over time, were found less frequently among those infected during the first few years of life. The presence of 5 or more depressed facial scars 2 mm or more in diameter at the base was accepted as indicating a probable previous attack of smallpox

(see Plate 24.4) and such persons were carefully interrogated to determine the time of occurrence of the illness and its cause. Contrary to what might be expected, it was found that, as mentioned before, most villagers generally remembered precisely when an individual had acquired the disease which caused the scars. Chickenpox also sometimes leaves residual scars, but it was unusual to find 5 or more scars on the face. Facial scarring or pitting resulting from other causes, such as burns and acne and other skin diseases, could usually be distinguished by experienced observers, but these cases too were investigated by interrogation and, where possible, by review of the medical records.

Variola minor, which was prevalent in Brazil and in several parts of Africa during the period of the Intensified Smallpox Eradication Programme, caused far less scarring. A careful follow-up study in Somalia (Ježek & Hardjotanojo, 1980) showed that 5 or more facial pockmarks could be detected in only 7% of patients seen 1 year after recovery. Pockmark surveys were of little use and were not carried out in countries such as Brazil, Ethiopia and Somalia, in which only variola minor had occurred in recent years. A number of African countries had experienced both

variola major and variola minor and in many the pockmark surveys were supplemented by surveillance of cases of chickenpox (see below).

When a pockmarked person was found, the dating of his illness became a matter of importance; if it was more recent than the last known case of smallpox, the adequacy of the surveillance system was open to question. The surveys concentrated on the examination of children, as their illnesses were usually more recent than those of adults. Failure to find pockmarks in any children born since the occurrence of the last known case in the country provided important evidence that transmission of variola major had been interrupted.

A widely varying incidence of pockmarks was observed in pockmark surveys carried out by national teams in 34 African and 5 Asian countries. A relatively high incidence was found in schoolchildren in some countries, particularly where large outbreaks of variola major had occurred a few years before transmission had been interrupted. However, when the date of illness of each case was carefully investigated, no children were found whose illness was more recent than the last reported case.

In many countries the members of the international commission also carried out pockmark surveys during their field visits. The prevalence of facial pockmarks which they observed was often higher than that recorded during the national surveys, since they tended to focus on high-risk areas, such as those in which the last known cases of smallpox had occurred.

### Chickenpox Surveillance

Where variola minor was prevalent and residual pockmarks were uncommon, emphasis was placed on the surveillance of chickenpox cases, which were sometimes clinically confused with smallpox. It was thought that a surveillance system sensitive enough to detect a large proportion of chickenpox cases would, in all likelihood, detect smallpox, if it were present. Efforts were made to verify the diagnosis of a number of such cases, especially those which were severe or fatal, by the examination of scabs or vesicular fluid in the laboratories of WHO collaborating centres.

Both the fixed and the mobile health units sought to discover and report chickenpox

cases. In addition, some countries introduced the notification of chickenpox during the post-eradication period where previously this had not been required. The taking of specimens from at least one case in each outbreak, especially if a death had occurred, was requested and specimens were also obtained from patients who had not been vaccinated against smallpox and those with an extensive rash involving the palms and soles. In a few countries, a small reward was offered for the discovery of the first case of chickenpox in a previously unrecognized outbreak.

### Rumour Register

In 1974, a new device was introduced in India—a register in which all cases of smallpox were recorded, and later all cases of fever with rash. It was particularly effective in countries in which smallpox was then endemic—namely, certain Asian countries and in the Horn of Africa. Rumour registers (Plate 24.5) were maintained at both national and lower levels. At the regional level, health officials kept a record of all patients, including the full name, age, sex, village or locality, presence or absence of a vaccination scar, date, and data relevant to the illness. All cases entered in the register were investigated by qualified personnel. If there was any doubt regarding the diagnosis, a consultation was sought through the national surveillance organization and specimens were collected. All the information supplied by the regions was recorded in national registers.

### Specimens for Laboratory Diagnosis

Relatively few specimens were collected when smallpox was widespread because the diagnosis was usually obvious; if there was any doubt, cases were treated as smallpox. As the incidence fell to low levels, increasing numbers of specimens were taken and, as transmission came closer to being interrupted, specimens were collected from each suspected case.

In countries in which variola minor had been endemic, preparing for certification required the collection of large numbers of specimens from patients with chickenpox and with other types of fever with rash, and from other patients in whom smallpox was suspected. They were sought over a wide geographical area and especially in population

<sup>a</sup> Recorded by date of receipt in Geneva. Includes only specimens for which testing results were reported. Includes multiple specimens from the same individual if taken. Excludes serum, animal, varolation and other specimens associated with special studies.

<sup>b</sup> Of which positives for monkeypox by year numbered: 1970 (Zaire 1, Liberia 4, Sierra Leone 1), 1971 (Côte d'Ivoire 1, Nigeria 2), 1972(5), 1973(3), 1974(1), 1975(3), 1976(3), 1977(7), 1978 (Zaire 8, Benin 1), 1979 (Zaire 4, Cameroon 2).

Fig. 24.1. Number of specimens collected from cases of smallpox, suspected smallpox, chickenpox, or suspected monkeypox and tested by WHO collaborating centres, 1972-1979.

groups and regions considered most likely to harbour smallpox. Specimens were forwarded to Geneva and from there sent either to the WHO collaborating centre in Atlanta or to that in Moscow. The specimens were shipped and tested with the least possible delay and those given priority were dealt with immediately, the results being cabled to the field.

Table 24.1 shows the national origin of specimens tested between 1969 and the end of 1979. The number tested rose from 288 in 1974 to over 4200 in 1978 and 1979 (Fig. 24.1). The percentage of specimens in which variola virus was found was relatively large during the earlier years, but none was positive after October 1977. About three-quarters of the specimens collected in 1978 and 1979 came from Ethiopia, Kenya and Somalia, which had reported their last cases (of variola minor) in 1976 and 1977 and were preparing for certification in 1979. Most specimens came from cases of chickenpox, the virus of which does not grow on the chorioallantoic membrane of the chick embryo. However, electron microscopy showed that many of them contained herpesvirus particles (varicella virus).

### Publicity Campaigns and Rewards

Publicity campaigns aimed at encouraging people to report suspected cases and inform-

ing them that they would receive a reward if any of the cases turned out to be positive had been a feature of the eradication campaigns in the Indian subcontinent and the Horn of Africa and they continued until formal certification had occurred. In large urban centres, use was made of radio, newspapers, and television. In smaller villages and remote areas, leaflets and posters showing pictures of smallpox patients were more frequently used. Health unit personnel were encouraged to inquire about smallpox and other illnesses with fever and rash, and mobile teams repeatedly visited schools, markets and other places, where they informed the public about the disease, either in conversation or by loud hailer. In several countries so many posters and signs were fixed to walls that the smallpox teams were asked to desist because they were defacing the buildings.

The rewards were initially small but were gradually increased until they ultimately reached the sum of US\$1000, offered by WHO in 1978 (Plates 24.6 and 24.7). In their contacts with schoolchildren or other segments of the population, active search teams showed the smallpox recognition card, asked people what the disease was, when cases had last been seen, and whether there were any reports or rumours of smallpox or chickenpox in the area. The teams also inquired whether people knew where to report if they did know of such a case and also whether they knew about the reward and its value. Since the value of the reward was changed at intervals, the replies provided an indication of how recently information had been received about the campaign.

The reward system was not readily accepted in all countries, since some national health authorities feared that it would establish a precedent with regard to the reporting of other diseases, although in fact no evidence of this was subsequently found. In western Africa, for example, the offering of rewards was discussed at the coordination meeting in 1975, during preparations for certification, but was finally rejected. However, rewards became an important method of surveillance, especially in Asian countries.

For smallpox transmission to have continued without detection when a large proportion of the population knew about the disease and the reward appeared highly unlikely. Thus, many countries conducted surveys to assess what proportion of the population knew about smallpox and where to report a

### Rewards for Reporting Smallpox

The idea of offering a reward for information on cases that were proved to be smallpox originated in Indonesia, following the discovery that information on known smallpox cases had been suppressed by local officials because they feared punishment for failure to control the disease. It was taken up in most Asian countries in which smallpox was still endemic, and in some African countries. The reward was important in several areas of India, in which the reporting of cases by a health officer was taken as *prima facie* evidence that the vaccination campaign for which he was responsible had not been sufficiently thorough and he was punished for this by transfer or other means. By announcing that a reward would be given for reporting a case, the government made it quite clear that it wanted cases to be reported. Moreover, if health officers continued to suppress reports, lower-level staff anxious to receive the money bypassed them and reported the cases.

The size of the reward increased as the likelihood of finding a case of smallpox declined. The existence of a reward proved to be most effective in two ways: it increased the reporting of suspected cases of smallpox and, during active searches, questions aimed at discovering whether people knew of the reward proved an excellent method of assessing the effectiveness of search teams.

In April 1978, a coordination meeting was held in Nairobi, Kenya, to discuss preparations for the certification of the Horn of Africa. At that time 5 months had elapsed without a reported case of smallpox despite continuing surveillance in the Horn of Africa, as well as elsewhere in the world. One of the proposals discussed during the meeting was that a global WHO reward should be established to promote the reporting of smallpox. Reporters covering the meeting enthusiastically supported this idea. As a result of a recommendation from this meeting, the Thirty-first World Health Assembly in May 1978, in its resolution on smallpox (WHA31.54), requested the Director-General

"...to establish a reward of US\$1000 for the first person who, in the period preceding final certification of global eradication, reports an active case of smallpox resulting from person-to-person transmission and confirmed by laboratory tests, in the belief that such a reward will strengthen worldwide vigilance for smallpox as well as national surveillance in priority countries".

Thereafter, the reward was widely publicized through radio, newspapers, television, etc., and a specially designed poster (Plate 24.7) was distributed to all countries. Immediately after the announcement of the award, many suspected cases were reported to WHO Headquarters, not only from developing but also from developed countries, including France and the USA. All proved to be false alarms. The reward was never collected.

case, or had heard about the reward. The surveys were often combined with active searches for cases of unreported smallpox. In the more populous and more recently endemic countries these campaigns reached a very high proportion of the people.

outbreaks and data on precertification surveillance activities. These reports were submitted to the international commission at the beginning of its visit and provided the basic information needed for the planning of its field trips.

### Documentation

Each country expecting to be visited by a commission was asked by WHO to prepare a comprehensive report ("country report") containing demographic data, information on its notification and surveillance system, a description of its smallpox eradication programme, information about the most recent

### OPERATION OF INTERNATIONAL COMMISSIONS

The membership of all the international commissions is set out in Annex 24.1 and their operation is described in Chapters 25-27. General features of the method of selecting commission members, as developed after the certification of Indonesia, and their usual mode of operation, are outlined below.

## SMALLPOX SURVEILLANCE

## SURVEILLANCE DE LA VARIOLE

### REWARD US\$ 1000 RÉCOMPENSE

A reward has been established by the Director-General of WHO for the first person who, in the period preceding final certification of global eradication, reports an active case of smallpox resulting from person-to-person transmission and confirmed by laboratory tests.

(Resolution WHA31.54, World Health Assembly, 1978)

Le Directeur général de l'OMS a institué une récompense à attribuer à la première personne qui, au cours de la période précédant la certification définitive de l'éradication mondiale, signalerait un cas actif de variole résultant de la transmission d'un être humain à l'autre et confirmé par des essais de laboratoire.

(Résolution WHA31.54, Assemblée mondiale de la Santé, 1978)

SMALLPOX-FREE WEEKS WORLDWIDE

39 SEMAINES SANS CAS DE VARIOLE  
DANS LE MONDE

## LABORATORIES RETAINING VARIOLA VIRUS

## LABORATOIRES DÉTENANT ENCORE DU VIRUS VARIOLIQUE

With the interruption of transmission of smallpox in the world population, the only remaining possible source of infection will be laboratories still retaining stocks of the causative virus.

Accordingly, the Thirty-first World Health Assembly (1978) has requested that all laboratories retaining variola virus, except WHO Collaborating Centres, destroy their stocks or transfer them to a WHO Collaborating Centre. Of at least 76 laboratories identified by WHO to have variola virus since all countries and areas were polioed from 1975 to 1977, 57 had voluntarily transferred or destroyed their strains by the end of 1977. In 1978 five additional laboratories have disposed of their strains.

Instituto Adolfo Lutz, São Paulo (Brazil)

Laboratoire national de la Santé publique, Paris (France)

Microbiological Research Establishment, Porton Down, Salisbury (United Kingdom)

Virus Instituto Salud Pública, Lima (Peru)

Walter Reed Army Institute of Research, Washington (USA)

Currently there are at least 14 laboratories with variola virus (Table 1). China reports that more than one laboratory has this virus.

Security measures for such laboratories were recommended by a "Workshop Meeting on Safety Measures in Laboratories Retaining Variola Virus", convened by WHO in August 1977. With continued cooperation the number of laboratories retaining variola virus will be further reduced to not more than four WHO Collaborating Centres by 1980.

Avec l'arrêt de la transmission de la variole dans la population mondiale, la seule source possible d'infection sera constituée par les laboratoires détenant encore des stocks de virus pathogène.

Aussi la Trente et Uneième Assemblée mondiale de la Santé (1978) a-t-elle demandé à tous les laboratoires, autres que les centres collaborateurs de l'OMS, de détruire ou de transférer à un centre collaborateur leur stock de virus variolique. Sur au moins 76 laboratoires identifiés par l'OMS comme détenant du virus variolique depuis l'enquête conduite de 1975 à 1977 sur tous les pays et circonscriptions, 57 avaient volontairement transféré ou détruit leurs souches à la fin de 1977. En 1978, cinq autres laboratoires se sont défaits de leurs souches, soit:

Instituto Adolfo Lutz, São Paulo (Brésil)

Laboratoire national de la Santé publique, Paris (France)

Microbiological Research Establishment, Porton Down, Salisbury (Royaume-Uni)

Virus Instituto Salud Pública, Lima (Pérou)

Walter Reed Army Institute of Research, Washington (EUA)

Actuellement, il existe au moins 14 laboratoires qui possèdent du virus variolique (Tableau 1). La Chine signale que plus d'un laboratoire de ce pays détient le virus en question.

Un atelier sur les mesures de sécurité à appliquer dans les laboratoires conservant des stocks de virus variolique réuni par l'OMS en août 1977 a recommandé les mesures de sécurité à appliquer dans les laboratoires en cause. Grâce à un esprit de collaboration de toutes les parties, il n'y aura plus en 1980 que quatre laboratoires qui conserveront des stocks de virus variolique, il s'agira dans les quatre cas de centres collaborateurs de l'OMS.

Epidemiological notes contained in this number:

Adenovirus Infections, Legionnaire's Disease, *Neisseria gonorrhoeae*, Poliovirus Surveillance, Smallpox Surveillance, Surveillance of Animal Rabies, Surveillance of Nosocomial Infections, Viral Diseases Surveillance.

List of Newly Infected Areas, p. 228.

Informations épidémiologiques contenues dans ce numéro:

Infections à adénovirus, Maladie de l'American Legion, *Neisseria gonorrhoeae*, surveillance de la poliomyélite, surveillance de la rage animale, surveillance de la variole, surveillance des infections nosocomiales, surveillance des maladies à virus.

Liste des zones nouvellement infectées, p. 228.

**Plate 24.6.** The Weekly epidemiological record was used extensively to promote the certification activities by publishing pertinent information. The front page of the issue for 28 July 1978 announced the offer of a reward of US\$1000 for reporting an active case of smallpox and recorded that 39 weeks had passed since the last case in the world. The front-page article reported on laboratories that had disposed of their stocks of variola virus; such stocks were by then considered the only possible remaining source of infection.

**Plate 24.7.** Poster produced by WHO in mid-1978, publicizing the reward of US\$1000 for finding a confirmed case of smallpox.

## Membership

The timing of the visits to the countries by international commissions and their membership were decided by WHO in the course of discussions with national health authorities. Individuals were selected who would be critical in their assessments and whose views as experts would be respected both nationally and internationally. Some of those selected were experts in communicable disease control, others in virology or health management. On each commission, one or two members were appointed from the countries most at risk of importation of smallpox from the country or countries to be certified. As time passed a deliberate effort was also made to include in the international commissions experts from as many different countries as possible, so that the nature and extent of the efforts made to document the interruption of transmission would be widely known. Special care was taken in the selection of the chairman. Apart from the first international commission, in South America, the chairman was not a national of any country under review and, after the certification of Indonesia, officials from the country concerned were, with few exceptions, excluded from the international commissions. Exceptions were made for the single group of experts who, as members of separate international commissions, certified Bangladesh and Burma respectively, by including a Burmese member in the commission assessing the adjacent country of Bangladesh and a Bangladeshi as a member of the commission assessing Burma. In addition, a senior Indian military medical officer was included in the Indian commission, so that visits could be made to areas to which foreigners did not have access at that time.

After the appointment of the Global Commission for the Certification of Smallpox Eradication early in 1978, its members served as chairmen or members of almost all of the international commissions. In this way members of the Global Commission became familiar with the certification process at the country and regional levels. In all, 76 experts from 48 countries served on international commissions (see Annex 24.1).

## Mode of Operation

The principal aim of a commission's visit to a country was to evaluate the reliability of

D. HENROUD. TS/9

**Plate 24.8.** Holger B. Lundbeck (b. 1924), Director of the National Bacteriological Laboratory, Stockholm, participated in several international commissions for the certification of smallpox eradication and was an influential member of the Global Commission. He is shown here signing the scroll certifying eradication which is reproduced as the frontispiece of this book.

that country's report by interviewing health personnel and examining records at both central and peripheral levels, so as to ascertain whether smallpox transmission had been interrupted as claimed. It was recognized that no commission could expect to examine even a small proportion of the population of a country in order to confirm that none had smallpox. Moreover, if experts of the right calibre were to participate, it was appreciated that they would be unable to spend more than 3-4 weeks away from their normal place of work. The objective of an international commission was to assess the quality of the local surveillance programme and to determine whether cases of smallpox would have been detected if transmission had occurred during the preceding 2 years. In doing so, commission members themselves usually carried out their own, rather limited surveys.

In most instances preliminary visits by one or two of the commission's members (often

the chairman) were arranged by WHO so that they could examine the state of the documentation and recommend any additional measures which they thought were indicated.

After arrival in the country to be certified, the commission usually spent 2-3 days in the capital reviewing the country report. If several countries were involved, the commission selected a conveniently situated capital city for its initial meeting, during which it scrutinized all the country reports; it then divided up into several groups to visit individual countries, and finally reassembled to assess the findings and prepare a report. In each country, in order to visit as many areas as possible, the commissions usually divided themselves up into teams consisting of one or two members, the areas selected being those identified as having the least satisfactory documentation or as being at unusual risk. Members of the commission had both the right and the responsibility to decide exactly which areas, villages and health units they would visit each day. The teams travelled extensively in the field for 1-3 weeks before reconvening.

### PROCEDURES FOR GLOBAL CERTIFICATION

By June 1977, international commissions had already visited or were preparing to visit all the previously endemic countries and countries at special risk. However, there were other countries in which there was a need to determine what measures should be taken in order to certify that the transmission of smallpox had been interrupted for at least 2 years. Furthermore, there were several countries—China, Democratic Kampuchea, Iran, Iraq, Madagascar, Namibia, South Africa, Southern Rhodesia (Zimbabwe), the Syrian Arab Republic, Thailand and Viet Nam—for which the staff of the Smallpox Eradication unit needed outside advice on how best to deal with the situation. Clearly, countries such as Madagascar and Thailand would not be expected to undertake the same kind of precertification activities as had been carried out in the countries of western Africa, yet they could not be ignored. Others, such as Democratic Kampuchea, Namibia, South Africa and Southern Rhodesia (Zimbabwe), were not readily accessible to WHO staff.

Another important matter was the international credibility of a claim that smallpox

had been eradicated throughout the world. The problem was that, if the staff of the Smallpox Eradication unit themselves were to decide as to the data to be provided in confirmation of eradication, such a decision was open to criticism by government officials and health professionals around the world, since those responsible for a programme obviously have a stake in its success. However objective their judgements might be, other scientists would be justified in questioning that objectivity.

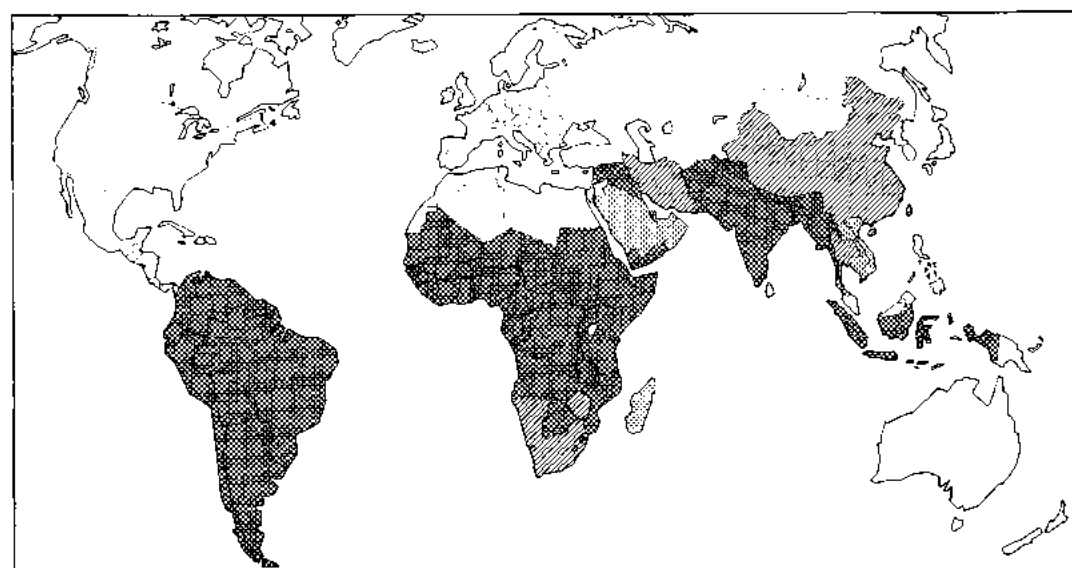

As has already been pointed out, the practical implications of the global eradication of smallpox were substantial. If the World Health Assembly were to accept that smallpox had been eradicated, this would mean that all preventive measures against the disease, including routine vaccination and international certificates of smallpox vaccination, could be abandoned. However, it was clear that these changes in well-established public health practices and the consequent financial savings would materialize only if the international community confidently accepted the assertion that smallpox had indeed been eradicated, first from countries, regions and continents and, finally, from the world. To gain such acceptance would not be a simple matter, for disbelief in the feasibility of smallpox eradication was common throughout the duration of the Intensified Smallpox Eradication Programme.

### Consultation on the Worldwide Certification of Smallpox Eradication

The practical solution to the problems described above was to set up a global commission of respected scientists which, as one of its functions, could advise WHO as to what data should be collected, for clearly this was a matter of judgement. Eventually, when such outside experts were fully satisfied that global eradication had been achieved, this conclusion would have been reached, not by WHO itself or by putting together the reports of a series of international commissions each dealing with one or a few countries, but by an international group of senior scientists and administrators capable of taking a global view of the problem.

To obtain advice on how best to achieve the certification of global eradication, the Director-General of WHO convened a consultation which was held in Geneva on 11-13

-  **Category 1** – **Formal certification by international commissions** of experts visiting the countries concerned and assessing their smallpox-free status by examining records and making field visits to determine whether surveillance activities would have been adequate to detect a case of smallpox if one had occurred during the previous 2 years.
-  **Category 2** – **Certification by the visit of selected experts** to verify and document the smallpox incidence since 1960, the last known outbreak and control measures employed, and procedures for handling suspected cases.
-  **Category 3** – **Certification through submission of detailed country reports.**
-  **Category 4** – **Official statements by countries** declaring their smallpox-free status during the previous 2 years and signed by government health authorities.

Fig. 24.2. Methodologies used for the certification of smallpox eradication in various categories of countries.

October 1977. The participants (Annex 24.2) included 17 experts on epidemiology, virology and public health administration from 15 countries: 3 from Africa, 3 from the Americas, 4 from Asia, 6 from Europe and 1 from Oceania. During the succeeding 2 years, most of the participants in the consultation served on the Global Commission for the Certification of Smallpox Eradication. Documentation for the meeting had been prepared by the staff of the Smallpox Eradication unit, and the consultation made important recommendations (WHO/SE/77.98) as to how certification should proceed so that the stage could be reached, as quickly as possible, at which it could be certified that smallpox had been eradicated globally. For this purpose, the countries of the world were divided into three categories; a fourth was subsequently added

by the Global Commission (Fig. 24.2). The various categories are discussed below.

*Category 1—Formal certification by international commissions*

The most stringent assessment was required in countries in which smallpox was endemic at the inception of the Intensified Smallpox Eradication Programme in 1967, or had become endemic since then. For such countries, the consultation recommended that the established procedure of formal certification by designated international commissions should be carried out. In October 1977, when the consultation met, this formal certification had already been performed in South America (1973), Indonesia (1974), 15 countries in western Africa (1976),

Afghanistan and Pakistan (1976), 5 countries in south-eastern Asia (1977) and 9 countries in central Africa (1977) (see Plate 24.11). The additional countries scheduled for formal certification from November 1977 onwards were:

*South-eastern Asia:* Bangladesh and Burma (scheduled for November–December 1977).

*South-eastern Africa:* Malawi, Mozambique, the United Republic of Tanzania and Zambia (scheduled for March 1978).

*Eastern-central Africa:* Sudan and Uganda.

*Southern Africa, group I:* Angola, Botswana, Lesotho and Swaziland.

*Southern Africa, group II:* Namibia, South Africa and Southern Rhodesia (Zimbabwe). Because of political complexities (see Chapter 26) it was apparent by 1978 that it would be both difficult and time-consuming to organize the certification of these countries by international commissions. Instead they were investigated as set out for Category 2 countries (see below) and certified by the Global Commission.

*The Horn of Africa and neighbouring countries:* Democratic Yemen, Djibouti, Ethiopia, Kenya, Somalia and Yemen.

#### *Category 2 — Certification by the visit of selected experts*

The consultation considered that some countries in which smallpox was not endemic in 1967 required special consideration, short of a visit by an international commission, because of the inadequacy of surveillance and/or their proximity to areas in which smallpox had recently been endemic. For such countries, it was suggested that visits by international experts (subsequently Global Commission members or WHO consultants) and/or WHO epidemiologists should be arranged during 1978 in order to verify and document their smallpox eradication status. The countries in this category are discussed below.

*China.* Although it was widely believed that smallpox transmission had been interrupted in China in about 1960, the country did not become a member of WHO until 1972. Even as late as 1977, little information was available to WHO as to what had been achieved, or how, or when, except that smallpox had been eradicated in China in 1960 or thereabouts. Since it was the most populous country on earth, and one in which smallpox had been widespread for over 1800 years, the consulta-

tion believed that special investigations were needed to assure the international community that smallpox was no longer endemic there.

*Iran, Iraq and the Syrian Arab Republic.* Although endemic smallpox had been eliminated from these countries in 1963, 1959 and 1957 respectively, variola major had become established again in all of them between 1970 and 1972. Smallpox was first reintroduced into Iran from Afghanistan and subsequently spread into Iraq and the Syrian Arab Republic (see Chapter 23). Because of the extent and duration of the outbreak, the consultation suggested that each of these countries should be asked to submit a detailed report of its surveillance programme and smallpox eradication activities during at least the past 5 years, after which members of the consultation or its successor, the Global Commission, would visit each country to review the situation.

*Thailand.* Although smallpox had ceased to be endemic in Thailand in 1962, the good communications with Bangladesh and India indicated the need for special evaluation, particularly in the border area of Thailand, Burma and the Lao People's Democratic Republic, which was notoriously inaccessible.

#### *Category 3—Certification through submission of detailed country reports*

WHO was requested by the consultation to ask certain countries to provide detailed reports, including but not limited to data on the incidence of smallpox since 1960, an account of the last known outbreak and the control measures employed, and the method of approach to be adopted should a suspected case of smallpox be found. Several countries about which detailed information was not available to the Global Commission fell into this category and are discussed below.

*Gulf States: Bahrain, Kuwait, Oman, Qatar, Saudi Arabia and the United Arab Emirates.* These countries had been free of endemic smallpox since 1963 but had experienced sporadic importations up to 1971. The Secretariat-General for the Ministers of Health of the Arab States of the Gulf was asked to coordinate the preparation of special country reports from these States.

*South-east Asian countries.* Because fighting had been going on for so long, detailed information was lacking from Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam. A special report was

also requested from China (Province of Taiwan).

*Madagascar.* Although the last reported case of smallpox in Madagascar occurred in 1934, rumours had reached the consultation of outbreaks of a disease that might have been smallpox. A special report was therefore requested.

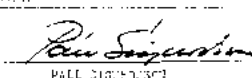

#### Category 4—Official statements by countries

In addition to these more stringent requirements, it was decided that every country and area should provide WHO with a signed statement that smallpox had not been present in that country or area during at least the preceding 2 years. Certification of freedom from smallpox by an international commission was considered to constitute such a statement.

#### Establishment and Responsibilities of the Global Commission

Finally, the consultation recommended that, since smallpox eradication was an unprecedented achievement, it should be promptly certified and appropriately recognized. For that reason, "... To assist in this effort and to provide authoritative endorsement, a formally constituted International Commission for the Global Certification of Smallpox Eradication (Global Commission) should be established by WHO to provide consultative assistance and verification of this event" (WHO/SE/77.98). Early in 1978 most of the participants in the consultation were designated by the Director-General of WHO as constituting the Global Commission for the Certification of Smallpox Eradication and at the same time a few new members were introduced (Annex 24.2; Plate 24.10).

Fenner, who had been Chairman of the consultation, was elected Chairman of the Global Commission, and acted in this capacity at the meetings in 1978 and 1979 (see below). Dr W. Koinange of Kenya was the Vice-Chairman at the 1977 consultation and Dr Jan Kostrzewski of Poland was Vice-Chairman at both meetings of the Global Commission. Arita, as Chief of the Smallpox Eradication unit, served as secretary both of the consultation and of the Global Commission. As has already been mentioned, Global Commission members were included in almost all of the 11 international commissions which met in 1978

DECLARATION OF SMALLPOX-FREE STATUS	
The Government of _____ (country)	
hereby declares that no case of smallpox has occurred in its territory during the previous two years	
The last case occurred in _____ (year if known)

 PAUL D'AUBERT SECRETARY GENERAL	

**Plate 24.9.** Official statements, like this one from Iceland, were received from 121 countries and territories declaring they had not had a case of smallpox for at least 2 years. They were accepted by the Global Commission for all countries other than the 79 where special measures were deemed necessary.

and 1979 to deal with specific geographical areas, an experience which further strengthened the assessment by the Global Commission of the progress of eradication as a whole.

The Global Commission met in Geneva in December 1978 and again in December 1979 to review certification activities in various countries in the four categories defined by the consultation and to consider other issues relevant to global certification. At the 1979 meeting, the Global Commission debated and approved its final report (World Health Organization, 1980), which was submitted to the Thirty-third World Health Assembly.

#### CHRONOLOGY OF CERTIFICATION

As has previously been noted, special measures had to be taken in 79 countries before the declaration of global smallpox eradication could be made. Between 1973 and 1979,

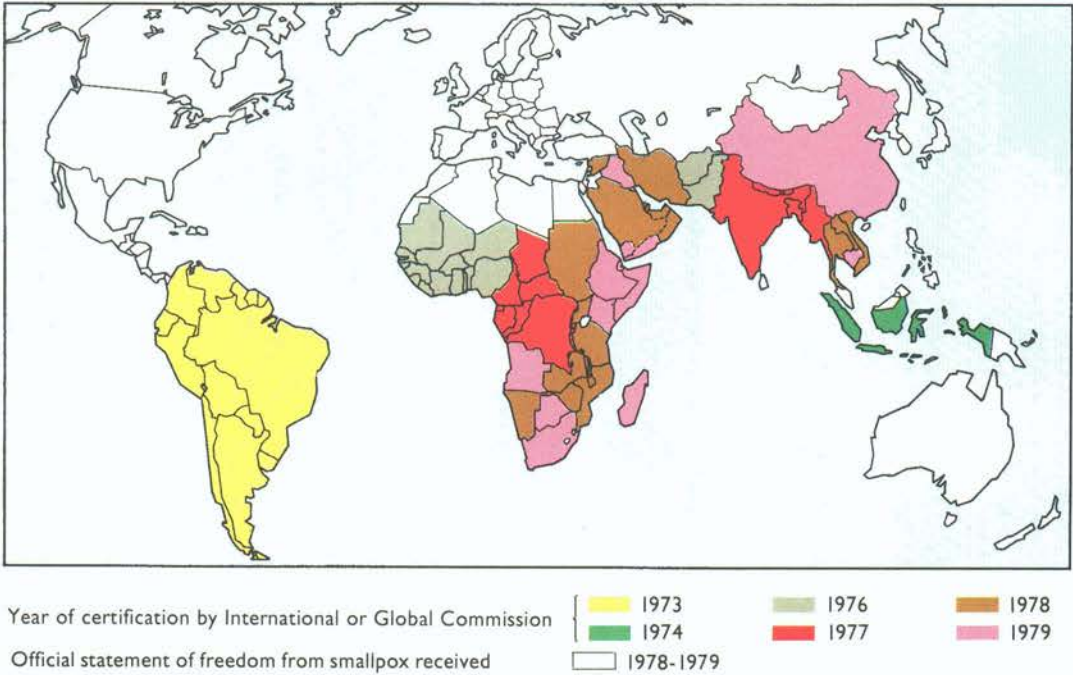

**Plate 24.10.** Participants at the meeting of the Global Commission for the Certification of Smallpox Eradication, 6-9 December 1979. Left to right, front row: Yemane Tekeste (Ethiopia), Z. Ježek (WHO), I. D. Ladnyi (WHO), I. Arita (WHO), Z. Islam (WHO), S. E. Woolnough (WHO), C. I. Sands (WHO); second row: **S. S. Marennikova (USSR)**, **J. Azurin (Philippines)**, **P. N. Burgasov (USSR)**, **F. Fenner (Australia)**, **J. Kostrzewski (Poland)**, **D. A. Henderson (USA)**, **W. Koinange (Kenya)**, Jiang Yutu (China); third row: A. I. Gromyko (WHO), **R. N. Basu (India)**, **J. M. Aashi (Saudi Arabia)**, **B. A. Rodrigues (Brazil)**, **R. Netter (France)**, **J. S. Moeti (Botswana)**, **Kalisa Ruti (Zaire)**, **P. N. Shrestha (Nepal)**, B. C. Dazo (WHO), M. C. de Souza (WHO), **Zhang Yihao (China)**, J. Magee (WHO); back row: G. Meiklejohn (USA), **P. F. Wehrle (USA)**, J. G. Breman (USA), **H. B. Lundbeck (Sweden)**, **K. R. Dumbell (United Kingdom)**, **I. Tagaya (Japan)**, **A. Deria (Somalia)**, J. L. Tulloch (WHO), R. N. Evans (WHO), J. F. Wickett (WHO). The names of the Commission members are in bold type.

therefore, the status of smallpox in these countries was assessed by WHO and by independent groups convened by the WHO Secretariat (Fig. 24.3). The eradication of smallpox in 63 of these countries was certified by international commissions; the situation in the other 16 (No. 53-64, 66-67 and 78-79) was evaluated by other means.

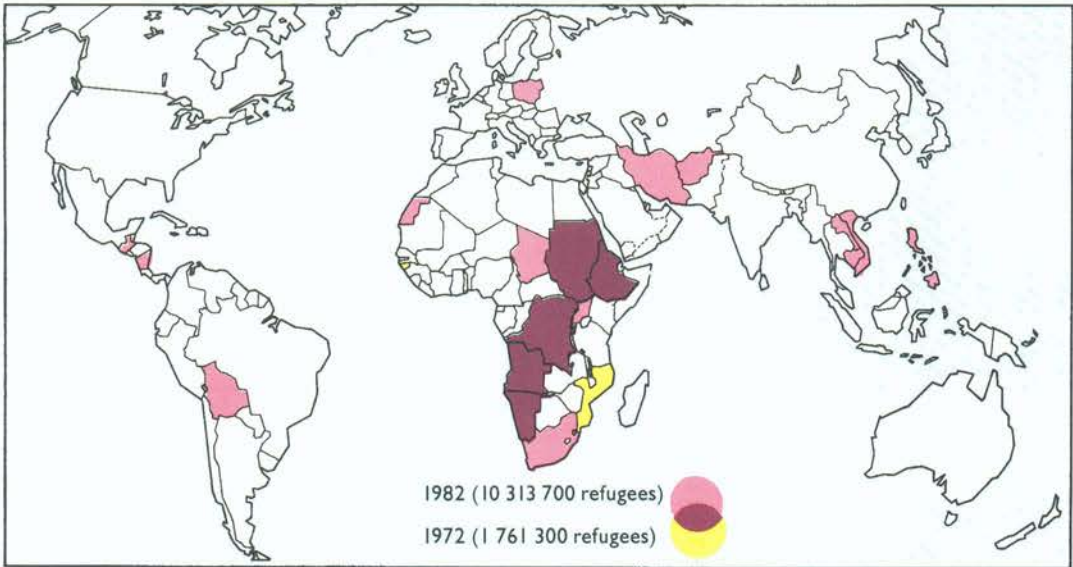

Of the 79 countries concerned, 31 had been certified by international commissions between 1973 and 1976 (see Plate 24.11), but from 1977 onwards certification activities were much accelerated in view of the fact that global eradication was imminent. The 1977 Consultation on the Worldwide Certification of Smallpox Eradication and the establishment of a Global Commission substantially promoted the prompt completion of these activities, since these bodies were a source of advice and recommendations.

In May 1978, when 49 of the 79 countries had already been certified, a document entitled *Methodology for Preparation of Appropriate Data for the [30] Countries Remaining to be Certified Free of Smallpox* (SME/78.6) was prepared by the staff of the Smallpox Eradication unit. On the basis of experience gained with previous certifications, the document set out the minimum requirements for the country reports, guidelines and standard forms for field activities such as pockmark surveys and chickenpox surveillance, and procedures for the collection and dispatch of laboratory specimens. It was distributed to all countries still to be certified and proved to be extremely useful for both health planners and field workers in their preparations for certification.

Despite the existence of many politically insecure areas in the late 1970s and the large

**Plate 24.11.** Chronological progress of certification in the 79 countries where special measures were necessary. All other countries provided an official statement that smallpox had not occurred in their country during the preceding 2 years.

**Plate 24.12.** Smallpox eradication, and its certification between 1973 and 1979, were conducted when the numbers of refugees in the world were growing constantly. This map shows the country of origin of refugees assisted by the Office of the United Nations High Commissioner for Refugees in 1972 and in 1982 (the purple shading indicates countries common to both years). Although it clearly depicts the magnitude of this distressing problem, it does not show some areas in which, before or between those years, the conditions that caused people to become refugees also made eradication work particularly difficult — e.g., Nigeria (1967–1968), Bangladesh (1970–1971), and the Horn of Africa (1974–1978).

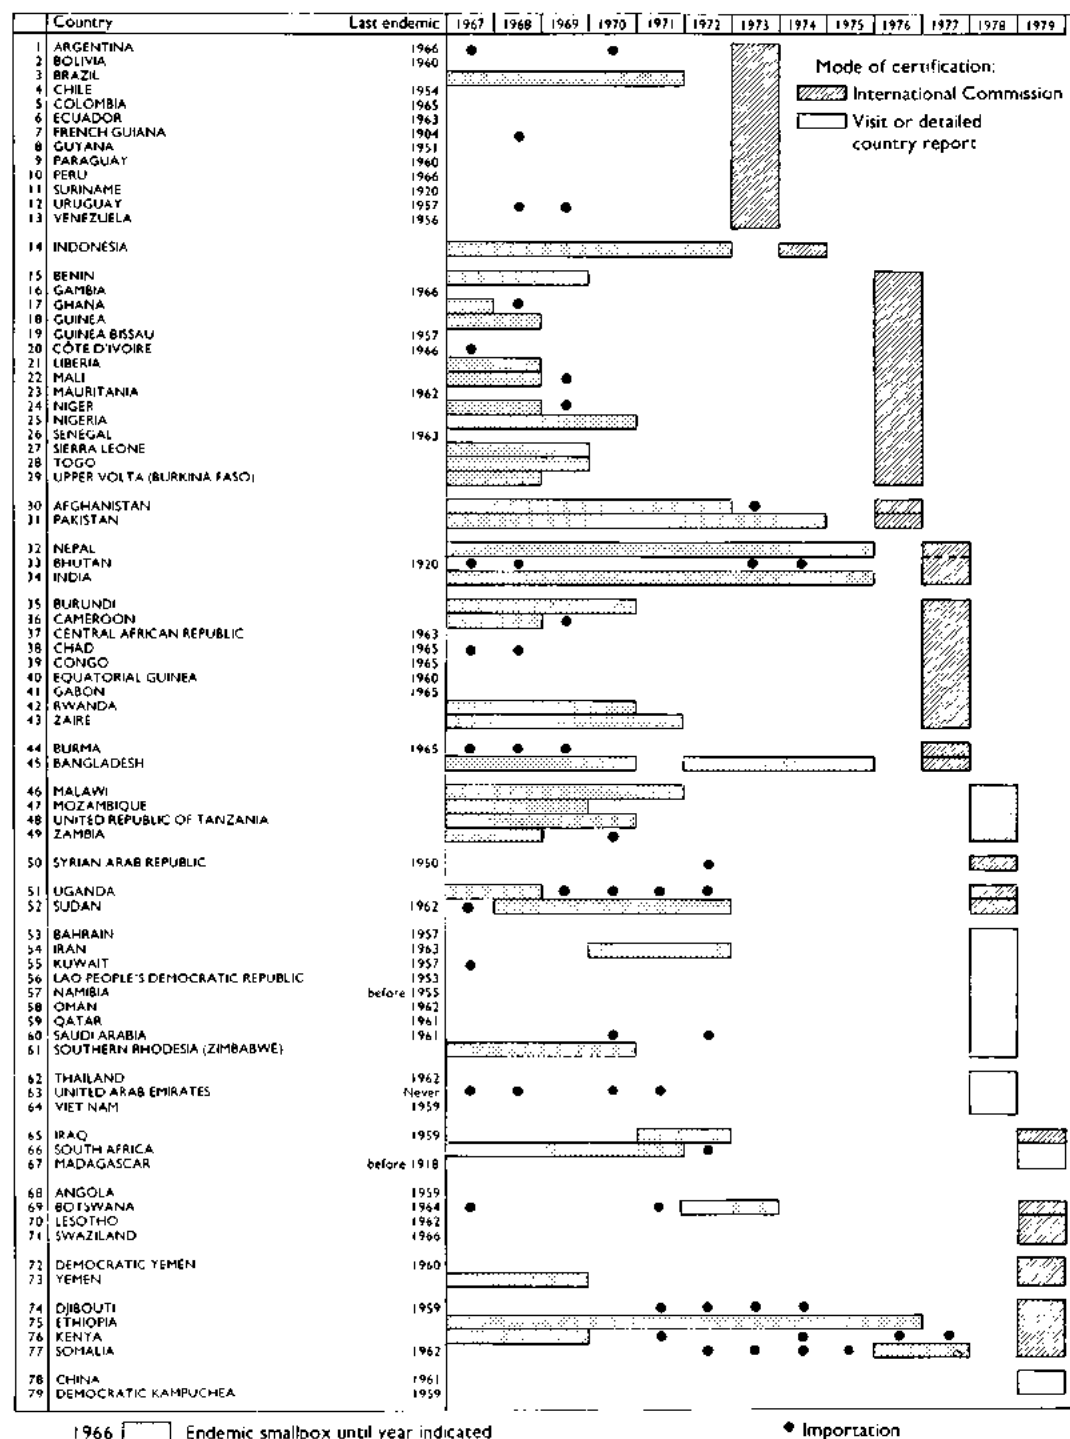

Fig. 24.3. Countries requiring special procedures for the certification of smallpox eradication. The year when the country ceased to be endemic, the year of the last known case, and the year and method of certification are also shown.

number of refugees, of whom there were ten times more in 1982 than in 1972 (see Plate 24.12), certification activities, including field visits by outside experts where necessary, proceeded surprisingly well, perhaps owing to the interest of the international community in this unprecedented event in the history of medicine.

Certification activities were strongly supported by a vigorous information campaign. From March 1978 to August 1980 a special information officer, Mr James Magee, was recruited to ensure good communications with major media agencies as well as medical periodicals. The goal of the information campaign was to reach beyond the scientific community with the news that:

(1) the world's last naturally occurring case of endemic smallpox had been found in Somalia on 26 October 1977;

(2) this was being confirmed globally by certification procedures involving an intensive search for cases; and

(3) it was expected that, if all went well, the target date for the declaration of global eradication, 26 October 1979—i.e., 2 years after the case in Somalia—would be met.

The benefits of eradication to the international community were stressed, including the end of the misery caused by this disease throughout human history and the enormous financial savings to the public health sector with the universal discontinuation of smallpox vaccination and associated control measures. Those with doubts were encouraged to speak out well in advance of the final global certification and countries were urged to change their legislation on smallpox vaccination at an early date.

The last certification activities by international commissions took place in October 1979 in the Horn of Africa—Djibouti, Ethiopia, Kenya, and Somalia, where, as has just been mentioned, the world's last case of endemic smallpox was discovered in October 1977. The 4 commissions that visited the countries of the Horn of Africa in October 1979 subsequently met in combined session in Nairobi, where they considered the region as a whole. On 26 October 1979, exactly 2 years after the onset of rash in the last case of endemic smallpox in the world, smallpox eradication was certified for Africa at a ceremony in which the Director-General of WHO and the directors of the Regional Offices

WHO SMALLPOX CONFERENCE, KINSHASA, 1968

**Plate 24.13.** Gordon Meiklejohn (b. 1911), Professor of Medicine at the University of Colorado, Denver, USA. Worked with Dr A. R. Rao in Madras in the early 1960s and served as a WHO consultant on smallpox almost every year from the mid-1960s, and for a full year in 1968–1969. He was a member of several international commissions for the certification of smallpox eradication and was responsible for the preparation of the first draft of the Final Report of the Global Commission.

for Africa and the Eastern Mediterranean participated.

Certification of the Horn of Africa left only 2 countries uncertified, China and Democratic Kampuchea. However, in November 1979, a report prepared after the visit of a WHO team to China became available and the smallpox situation in Democratic Kampuchea was clarified. On 9 December 1979, at its last meeting in Geneva, the Global Commission agreed to certify smallpox eradication in these 2 countries.

By the end of 1979 all other countries—i.e., excluding those visited by the international commissions or certified by the Global Commission on the basis of other evidence—had submitted to WHO their signed declarations that no cases of smallpox had occurred during at least 2 years. The requirements for global certification recommended by the 1977 Consultation on the Worldwide Certification of Smallpox Eradication had thus been met.

### DECLARATION OF THE GLOBAL ERADICATION OF SMALLPOX

The ultimate responsibility of the Global Commission, once it was satisfied that world-

The Thirty-third World Health Assembly, on this the 8th day of May 1980;

Having considered the developments and results of the global programme on smallpox eradication initiated by WHO in 1958 and intensified since 1967;

1. DECLARES SOLEMNLY THAT THE WORLD AND ALL ITS PEOPLES HAVE WON FREEDOM FROM SMALLPOX, WHICH WAS A MOST DEVASTATING DISEASE SWEEPING IN EPIDEMIC FORM THROUGH MANY COUNTRIES SINCE EARLIEST TIME, LEAVING DEATH, BLINDNESS AND DISFIGUREMENT IN ITS WAKE AND WHICH ONLY A DECADE AGO WAS RAMPANT IN AFRICA, ASIA AND SOUTH AMERICA;
2. EXPRESSES ITS DEEP GRATITUDE TO ALL NATIONS AND INDIVIDUALS WHO CONTRIBUTED TO THE SUCCESS OF THIS NOBLE AND HISTORIC ENDEAVOUR;
3. CALLS THIS UNPRECEDENTED ACHIEVEMENT IN THE HISTORY OF PUBLIC HEALTH TO THE ATTENTION OF ALL NATIONS, WHICH BY THEIR COLLECTIVE ACTION HAVE FREED MANKIND OF THIS ANCIENT SCOURGE AND, IN SO DOING, HAVE DEMONSTRATED HOW NATIONS WORKING TOGETHER IN A COMMON CAUSE MAY FURTHER HUMAN PROGRESS.

**Plate 24.14.** Resolution WHA33.3, the formal declaration of the eradication of smallpox, based on the report of the Global Commission to the Director-General of WHO, was adopted unanimously by the Thirty-third World Health Assembly on 8 May 1980.

En la séance qu'ils ont présidée ont approuvé les deux paragraphes.

Dr A.-R. A. Al-Awadi

Président de la 33ème Assemblée  
mondiale de la Santé

A handwritten signature in black ink, appearing to read "A. Al-Awadi".

Dr Halfdan Mahler

Directeur général de l'Organisation  
mondiale de la Santé

A handwritten signature in black ink, appearing to read "H. Mahler".

A Genève, le 24 mai 1969

**Plate 24.15.** As the President of the Thirty-third World Health Assembly, Dr A.-R. A. Al-Awadi, and the Director-General of WHO, Dr Halfdan Mahler, signed resolution WHA33.3, the President remarked: "While doctors sign the death certificates of people, today we are signing the death certificate of a disease".

WHO / J. GERMAIN

**Plate 24.16.** The ceremony of the declaration of global eradication of smallpox, on 8 May 1980, during the eighth plenary meeting of the Thirty-third World Health Assembly. **A:** Dr Frank Fenner (inset), Chairman of the Global Commission, addressed the Assembly and handed to the President the scroll that had been signed by the members of the Commission (see frontispiece). **B:** The President of the Assembly, Dr A-R. A. Al-Awadi, signing resolution WHA33.3, with the Director-General of WHO, Dr Halfdan Mahler, looking on.

wide eradication of smallpox had been achieved, was to document the reasons for its decision in a way that would allow the World Health Assembly to declare that smallpox had been eradicated. In addition, it was important that a post-eradication strategy should be planned and machinery developed to implement it.

During 1979, with the help of Dr Gordon Meiklejohn, a WHO consultant, the Smallpox Eradication unit drafted a report for consideration by the Global Commission. This was reviewed in detail by the 12 members of the Global Commission present in Nairobi in October 1979 (see Chapter 27), and the revised report was the main subject of discussion at the 4-day final meeting of the Global Commission in December 1979. The final report (World Health Organization, 1980) outlines the criteria on the basis of

which all members of the Global Commission signed a document proclaiming the global eradication of smallpox (see frontispiece). It also contained 19 recommendations covering all aspects of a post-eradication strategy (see Chapter 28) designed to ensure that all the countries of the world could remain confident that smallpox had indeed been eradicated.

On 8 May 1980 the Thirty-third World Health Assembly reviewed the Global Commission's report and declared that smallpox had been eradicated throughout the world. There were two resolutions: resolution WHA33.3 (see Plates 24.14–24.16) declared that the global eradication of smallpox had been achieved and resolution WHA33.4 endorsed the Global Commission's recommendations on policy for the post-eradication era (see Chapter 28).

#### ANNEX 24.1. MEMBERSHIP OF INTERNATIONAL COMMISSIONS FOR THE CERTIFICATION OF SMALLPOX ERADICATION

The positions held by members at the time of the international commissions give some indication of their standing and expertise. Members of the Global Commission who were also members of international commissions both before and after the establishment of the Global Commission are indicated by the letters GC in parentheses after their names.

##### 1. SOUTH AMERICA: 12–25 August 1973 (PAHO document CD22/19)

Dr A. N. Bica	Secretary of Public Health, Ministry of Health, Rio de Janeiro, Brazil ( <i>Chairman</i> )
Dr F. J. C. Cambournac	Director, Institute of Hygiene and Tropical Medicine, Lisbon, Portugal
Dr E. Echezuria	Chief, Department of Demography and Epidemiology, Ministry of Health, Caracas, Venezuela ( <i>Rapporteur</i> )
Dr J. D. Millar	Director, State and Community Services Division, Center for Disease Control, Atlanta, GA, USA
Dr R. J. Wilson	Chairman, Connaught Medical Research Laboratories Ltd, University of Toronto, Canada

##### 2. INDONESIA: 15–25 April 1974 (WHO/SE/74.68)

Dr N. McK. Bennett	Specialist Physician and Deputy Superintendent, Fairfield Hospital, Melbourne, Australia
Dr J. J. Dizon	Chief of Disease Intelligence, Disease Intelligence Centre, Department of Health, Manila, Philippines
Dr J. S. Gill	Assistant Director, Health and Epidemiology, Ministry of Health, Kuala Lumpur, Malaysia ( <i>Rapporteur</i> )
Dr S. Kumarapathy	Senior Registrar, Quarantine and Epidemiology, Environmental Public Health Division, Ministry of Environment, Singapore

6. CENTRAL AFRICA: 6–30 June 1977 (AFR/Smallpox/86)  
Countries included: Burundi, Cameroon, Central African Republic, Chad, Congo, Equatorial Guinea, Gabon, Rwanda and Zaire.
- |                 |  |
|-----------------|--|
| Dr P. Agbodjan  | Chief, Major Endemic Diseases Service, General Directorate for Health, Lomé, Togo  |
| Dr J. G. Breman | Epidemic Intelligence Officer (Michigan Department of Public Health), Bureau of Epidemiology, Center for Disease Control, Atlanta, GA, USA |

Dr E. Coffi	Director, Institute of Hygiene, Ministry of Public Health, Abidjan, Côte d'Ivoire
Dr F. Dekking	Health Science Laboratory, University of Amsterdam, Netherlands
Dr A. K. M'Baye	Chief Medical Officer, Major Endemic Diseases Service, and Deputy Director of Public Health, Dakar, Senegal ( <i>Chairman</i> )
Dr R. Netter (GC)	Director-General, National Health Laboratory, Paris, France ( <i>Rapporteur</i> )
Dr M. Yekpe	Chief, Communicable Diseases Service, Ministry of Public Health, Cotonou, Benin

## 7. INDIA: 4-23 April 1977 (SEA/Smallpox/78)

NEPAL: 4-13 April 1977 (SEA/Smallpox/80)

BHUTAN: 28 March-1 April 1977; 22 April 1977 (SEA/Smallpox/80)

*India and Bhutan*

Dr J. Červenka	Chief (Epidemiology), Institute of Epidemiology and Microbiology, Bratislava, Czechoslovakia
Dr W. A. B. de Silva	Deputy Director (Planning), Ministry of Health, Colombo, Sri Lanka
Dr F. Fenner (GC)	Director, Centre for Resource and Environmental Studies, The Australian National University, Canberra, Australia ( <i>Rapporteur</i> )
Dr H. Flamm	Institute of Hygiene, University of Vienna, Austria
Lt.-Gen. R. S. Hoon	Director-General, Armed Forces Medical Services, New Delhi, India
Dr T. Kitamura	Chief, Division of Poxviruses, National Institute of Health, Tokyo, Japan
Dr W. Koinange (GC)	Director, Division of Communicable Disease Control, Ministry of Health, Nairobi, Kenya
Dr J. Kostrzewski (GC)	Secretary, Medical Section, Polish Academy of Sciences, Warsaw, Poland ( <i>Chairman</i> )
Dr H. B. Lundbeck (GC)	Director, National Bacteriological Laboratory, Stockholm, Sweden
Dr A. M. Mustaqul Huq	Director of Health Services (Preventive), Ministry of Health, Dhaka, Bangladesh
Dr D. M. Mackay	Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, London, England
Dr M. F. Polak	Scientific Officer, Faculty of Medicine, Catholic University, Nijmegen, Netherlands
Dr R. Roashan	President, Foreign Relations Department, Ministry of Public Health, Kabul, Afghanistan
Dr D. J. Sencer	Director, Center for Disease Control, Atlanta, GA, USA
Dr U Thein Nyunt	Director, Disease Control, Ministry of Health, Rangoon, Burma
Dr V. M. Zhdanov	Director, Institute of Virology, Academy of Medical Sciences, Moscow, USSR

*Nepal*

Dr T. Kitamura	Chief, Division of Poxviruses, National Institute of Health, Tokyo, Japan
Dr J. Kostrzewski (GC)	Secretary, Medical Section, Polish Academy of Sciences, Warsaw, Poland ( <i>Chairman</i> )
Dr D. M. Mackay	Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, London, England ( <i>Rapporteur</i> )

## 8. BURMA: 21-30 November 1977 (SEA/Smallpox/83)

Dr S. Jatanasen	Director, Division of Epidemiology, Ministry of Public Health, Bangkok, Thailand
Dr A. D. Langmuir	Professor, Harvard University Medical School, Department of Preventive and Social Medicine, Boston, MA, USA ( <i>Secretary</i> )
Dr C. Lerche	Director, National Institute of Public Health, Oslo, Norway
Dr H. von Magnus	Head, Department of Epidemiology, State Serum Institute, Copenhagen, Denmark ( <i>Rapporteur</i> )
Dr A. M. Mustaqul Huq	Director of Health Services (Preventive), Ministry of Health, Dhaka, Bangladesh
Dr I. F. Setiady	Director, Epidemiology and Quarantine, Ministry of Health, Jakarta, Indonesia ( <i>Chairman</i> )
Dr M. I. D. Sharma	Emeritus Medical Scientist, New Delhi, India
Dr P. N. Shrestha (GC)	Chief, Smallpox Eradication Project, Department of Health Services, Kathmandu, Nepal
Dr U Thein Nyunt	Director, Disease Control, Ministry of Health, Rangoon, Burma

## 9. BANGLADESH: 1-14 December 1977 (SEA/Smallpox/84)

Dr S. Jatanasen	Director, Division of Epidemiology, Ministry of Public Health, Bangkok, Thailand
Dr A. D. Langmuir	Professor, Harvard University Medical School, Department of Preventive and Social Medicine, Boston, MA, USA ( <i>Chairman</i> )
Dr C. Lerche	Director, National Institute of Public Health, Oslo, Norway
Dr H. von Magnus	Head, Department of Epidemiology, State Serum Institute, Copenhagen, Denmark ( <i>Rapporteur</i> )
Dr A. M. Mustaqul Huq	Director of Health Services (Preventive), Ministry of Health, Dhaka, Bangladesh
Dr I. F. Setiady	Director, Epidemiology and Quarantine, Ministry of Health, Jakarta, Indonesia
Dr M. I. D. Sharma	Emeritus Medical Scientist, New Delhi, India
Dr P. N. Shrestha (GC)	Chief, Smallpox Eradication Project, Department of Health Services, Kathmandu, Nepal
Dr U Thein Nyunt	Director, Disease Control, Ministry of Health, Rangoon, Burma

## 10. MALAWI, MOZAMBIQUE, UNITED REPUBLIC OF TANZANIA and ZAMBIA: 6-29 March 1978 (AFR/Smallpox/87)

Dr M. Davies	Chief Medical Officer, Ministry of Health, Freetown, Sierra Leone
Dr Z. M. Dlamini	Senior Medical Officer of Health, Ministry of Health, Mbabane, Swaziland
Dr J. A. Espmark	Department of Virology, State Laboratory of Biology, Stockholm, Sweden
Dr F. Fenner (GC)	Director, Centre for Resource and Environmental Studies, The Australian National University, Canberra, Australia ( <i>Rapporteur</i> )
Dr J. S. Moeti (GC)	Director of Medical Services, Ministry of Health, Gaborone, Botswana ( <i>Chairman</i> )

## 11. IRAQ: 5-15 October 1978 (WHO/SE/78.127)

and

## 12. SYRIAN ARAB REPUBLIC: 15-22 October 1978 (WHO/SE/78.126)

Dr R. Netter (GC)	Director-General, National Health Laboratory, Paris, France ( <i>Chairman</i> )
Dr M. Chamsa	Assistant Director, Organization of Medical Services, Red Lion and Sun Society of Iran, Teheran, Iran

## 13. UGANDA: 11-27 October 1978 (AFR/Smallpox/88)

Dr A. Deria (GC)	Director, Department of Public Health, Ministry of Health, Mogadishu, Somalia ( <i>Chairman</i> )
Dr Kalisa Ruti (GC)	Medical Director, Expanded Programme on Immunization, Department of Public Health, Kinshasa, Zaire ( <i>Rapporteur</i> )
Dr Y. P. Rikushin	Chief, Department of Epidemiology, Pasteur Institute, Leningrad, USSR

## 14. SUDAN: 15-29 November 1978 (WHO/SE/79.134)

Dr A. M. Fergany	Adviser, Ministry of Health, Oman ( <i>Chairman</i> )
Dr W. Koinange (GC)	Chief Deputy Director of Medical Services, Ministry of Health, Nairobi, Kenya
Dr C. Lerche	Director, National Institute of Public Health, Oslo, Norway ( <i>Vice-Chairman</i> )
Dr S. S. Marennikova (GC)	Chief, Laboratory of Smallpox Prophylaxis, Moscow Research Institute for Viral Preparations, Moscow, USSR
Dr G. Meiklejohn	Professor of Medicine, University of Colorado Medical Center, Denver, CO, USA ( <i>Rapporteur</i> )
Dr D. A. Robinson	Community Physician, Communicable Disease Surveillance Centre, London, England
Ato Yemane Tekeste	Project Manager, Smallpox Eradication Programme, Addis Abeba, Ethiopia

## 15. ANGOLA: 5-16 February 1979 (AFR/Smallpox/89)

Dr Kalisa Ruti (GC)	Medical Director, Expanded Programme on Immunization, Department of Public Health, Kinshasa, Zaire ( <i>Co-Rapporteur</i> )
Dr Bichat A. Rodrigues (GC)	Regional Coordinator for the South-East Region, Ministry of Health, Brasilia, Brazil ( <i>Chairman</i> )
Dr Cabral A. J. Rodrigues	National Director of Preventive Medicine, Secretariat for International Cooperation, Maputo, Mozambique ( <i>Co-Rapporteur</i> )

## 16. BOTSWANA, LESOTHO AND SWAZILAND: 5-23 March 1979 (AFR/Smallpox/90)

Dr D. Chilemba	Chief Medical Officer, Ministry of Health, Lilongwe, Malawi
Dr A. Deria (GC)	Director, Department of Public Health, Ministry of Health, Mogadishu, Somalia
Dr P. E. M. Fine	Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, London, England
Dr W. Koinange (GC)	Chief Deputy Director of Medical Services, Ministry of Health, Nairobi, Kenya ( <i>Chairman</i> )
Dr G. Meiklejohn	Professor of Medicine, University of Colorado Medical Center, Denver, CO, USA ( <i>Rapporteur</i> )

Dr J. Kostrzewski (GC)	Secretary, Medical Section, Polish Academy of Sciences, Warsaw, Poland
Dr I. Noormahomed	Deputy National Director of Preventive Medicine, Ministry of Health, Maputo, Mozambique
Dr D. A. Robinson	Epidemiologist, Communicable Disease Surveillance Centre, London, England
Dr A. A. Stroganov	Assistant Professor, Central Institute for Advanced Medical Training, Communicable Disease Department, Moscow, USSR

21. KENYA: 1-19 October 1979 (WHO/SE/79.149)

Dr R. N. Basu (GC)	Assistant Director-General of Health Services, Directorate General of Health Services, New Delhi, India ( <i>Chairman</i> )
Dr Kalisa Ruti (GC)	Medical Director, Expanded Programme on Immunization, Department of Public Health, Kinshasa, Zaire
Dr S. S. Marennikova (GC)	Chief, Laboratory of Smallpox Prophylaxis, Moscow Research Institute for Viral Preparations, Moscow, USSR
Dr G. Meiklejohn	Professor of Medicine, University of Colorado Medical Center, Denver, CO, USA ( <i>Rapporteur</i> )
Dr J. S. Moeti (GC)	Senior Medical Officer of Health, Ministry of Health, Gaborone, Botswana

22. SOMALIA: 1-21 October 1979 (WHO/SE/79.146)

Dr J. M. Aashi (GC)	Assistant Director-General of Preventive Medicine, Ministry of Health, Riyadh, Saudi Arabia
Dr Z. M. Dlamini	Director of Medical Services, Ministry of Health, Mbabane, Swaziland
Dr T. J. Geffen	Director, Communicable Diseases Division, Department of Health and Social Security, London, England ( <i>Rapporteur</i> )
Dr H. B. Lundbeck (GC)	Director, National Bacteriological Laboratory, Stockholm, Sweden ( <i>Chairman</i> )
Dr J. D. Millar	Assistant Director for Public Health Practice, Center for Disease Control, Atlanta, GA, USA
Dr P. N. Shrestha (GC)	Chief, Planning Division, Tribhuvan University Institute of Medicine, Kathmandu, Nepal

**ANNEX 24.2. PARTICIPANTS IN THE CONSULTATION ON THE WORLDWIDE CERTIFICATION OF SMALLPOX ERADICATION AND MEMBERS OF THE GLOBAL COMMISSION**

The numbers in parentheses have the following significance:

- (1) participated in the 1977 Consultation;
- (2) attended the 1978 meeting of the Global Commission;
- (3) attended the 1979 meeting of the Global Commission.

**Participants in the Consultation and Members of the Global Commission**

Dr J. M. Aashi (1, 2, 3)	Assistant Director-General of Preventive Medicine, Ministry of Health, Riyadh, Saudi Arabia
Dr J. Azurin (1, 2, 3)	Under-Secretary of Health, Department of Health, Manila, Philippines
Dr R. N. Basu (1, 2, 3)	Assistant Director-General of Health Services, Directorate General of Health Services, New Delhi, India

Dr P. N. Burgasov (2, 3)	Deputy Minister of Health, Moscow, USSR
Dr H. Corral (1)	Director-General, Ministry of Health, Quito, Ecuador
Dr A. Deria (1, 2, 3)	Director, Department of Public Health, Ministry of Public Health, Mogadishu, Somalia
Dr K. R. Dumbell (1, 2, 3)	Head, Department of Virology, The Wright-Fleming Institute of Microbiology, St Mary's Hospital Medical School, London, England
Dr F. Fenner (1, 2, 3; Chairman: 1, 2, 3)	Director, Centre for Resource and Environmental Studies, The Australian National University, Canberra, Australia
Dr D. A. Henderson (1, 2, 3)	Dean, School of Hygiene and Public Health, The Johns Hopkins University, Baltimore, MD, USA
Dr Kalisa Ruti (3)	Medical Director, Expanded Programme on Immunization, Kinshasa, Zaire
Dr J. Kilgour (1)	Head, International Health Division, Department of Health and Social Security, London, England
Dr W. Koinange (1, 2, 3; Vice-Chairman: 1)	Director, Division of Communicable Disease Control, Ministry of Health, Nairobi, Kenya
Dr J. Kostrzewski (1, 2, 3; Vice-Chairman: 2, 3)	Secretary, Medical Section, Polish Academy of Sciences, Warsaw, Poland
Dr H. B. Lundbeck (1, 2, 3)	Director, National Bacteriological Laboratory, Stockholm, Sweden
Dr S. S. Marennikova (1, 2, 3)	Chief, Laboratory of Smallpox Prophylaxis, Moscow Research Institute for Viral Preparations, Moscow, USSR
Dr J. S. Moeti (1, 2, 3)	Senior Medical Officer of Health, Ministry of Health, Gaborone, Botswana
Dr C. Mofidi (1, 2)	Minister of Higher Education and Science, Teheran, Iran
Dr R. Netter (1, 2, 3)	Director-General, National Health Laboratory, Paris, France
Dr Bichat A. Rodrigues (3)	Executive Secretary, National Council of Health, Brasilia, Brazil
Dr P. N. Shrestha (2, 3)	Chief, Planning Division, Tribhuvan University Institute of Medicine, Kathmandu, Nepal
Dr I. Tagaya (2, 3)	Director, Department of Enteroviruses, National Institute of Health, Tokyo, Japan
Dr P. F. Wehrle (1, 2, 3; Rapporteur: 1, 2, 3)	Hastings Professor of Pediatrics, Los Angeles County—University of Southern California Medical Center, Los Angeles, CA, USA
Dr Zhang Yihao (3)	Deputy Director, National Serum and Vaccine Institute, Beijing, China

#### WHO Advisers

Dr H. Corral (1)	Director-General, Ministry of Health, Quito, Ecuador
Dr W. H. Foege (2)	Director, Center for Disease Control, Atlanta, GA, USA
Dr T. J. Geffen (2)	Director, Communicable Diseases Division, Department of Health and Social Security, London, England
Dr N. C. Grassie (2)	Epidemiologist, Douvaine, France
Dr Jiang Yu-tu (3)	Military Academy of Medical Sciences, Beijing, China
Dr G. Meiklejohn (2, 3)	Professor of Medicine, University of Colorado Medical Center, Denver, CO, USA
Dr W. Nicol (2)	Area Medical Officer, Birmingham, England
Dr A. G. Rangaraj (2)	Epidemiologist, Nilgiris District, Madras, India
Dr Parviz Rezai (2)	Deputy Director-General, Communicable Diseases Control and Malaria Eradication, Ministry of Health and Welfare, Teheran, Iran
Ato Yemane Tekeste (2, 3)	Programme Manager, Smallpox Eradication Programme, Addis Abeba, Ethiopia

**WHO Regional Office Staff***Africa:*

- Dr A. H. Abou-Gareeb (3), Director, Disease Prevention and Control, Brazzaville, Congo  
Dr C. Algan (1, 2), Medical Officer, Health Services, Brazzaville, Congo  
Dr Z. Islam (2, 3), Medical Officer, Epidemiological Surveillance of Communicable Diseases Project, Nairobi, Kenya  
Dr L. N. Khodakevich (2, 3), Interregional Medical Officer, Smallpox Eradication Project, Addis Abeba, Ethiopia

*Americas:*

- Dr J. Bond (3), Medical Officer, Communicable Diseases, Washington, DC, USA  
Dr C. H. Tigre (2), Scientist, Communicable Diseases, Washington, DC, USA  
Dr K. A. Western (1, 2), Chief, Communicable Diseases, Washington, DC, USA

*South-East Asia:*

- Dr L. N. Khodakevich (1), Medical Officer, Smallpox Eradication, New Delhi, India

*Europe:*

- Dr M. R. Radovanovic (1, 2), Medical Officer, Epidemiological Surveillance of Communicable Diseases, Copenhagen, Denmark

*Eastern Mediterranean:*

- Dr P. Chasles (1), Medical Officer, Communicable Diseases Prevention and Control, Alexandria, Egypt  
Dr F. Partow (2), Medical Officer, Communicable Diseases Prevention and Control, Alexandria, Egypt

*Western Pacific:*

- Dr B. C. Dazo (3), Scientist, Communicable Diseases, Manila, Philippines  
Dr R. R. Lindner (1), Medical Officer, Communicable Diseases, Manila, Philippines  
Dr Chin Wentao (2), Consultant Medical Officer, Communicable Diseases, Manila, Philippines

**WHO Headquarters Staff**

- Dr I. D. Ladnyi (1, 2, 3), Assistant Director-General  
Dr A. Zahra (2, 3), Director, Division of Communicable Diseases  
Dr I. D. Carter (2, 3), Epidemiological Surveillance of Communicable Diseases  
Dr H. J. Schlenszka (2), Legal Division  
Dr E. Shafa (1, 2), Expanded Programme on Immunization

*Smallpox Eradication unit:*

- Dr I. Arita (1, 2, 3), Chief Medical Officer  
Dr J. G. Breman (1, 2, 3), Medical Officer  
Mr R. N. Evans (2, 3), Technical Officer  
Dr A. I. Gromyko (1, 2, 3), Medical Officer  
Mr R. O. Hauge (1), Consultant Technical Officer  
Dr Z. Ježek (2, 3), Medical Officer  
Mr J. Magee (2, 3), Information Officer  
Dr J. L. Tulloch (2, 3), Consultant Medical Officer  
Mr J. F. Wickett (1, 2, 3), Administrative Officer

## INTRODUCTION

In the previous chapter we examined in broad terms the process by which the certification of smallpox eradication was undertaken, culminating in the adoption by the World Health Assembly on 8 May 1980 of a resolution declaring that smallpox had been eradicated throughout the world. In the present chapter and the two which follow, this process is examined in more detail. It is evident that the problems that occurred paralleled those encountered during the elimination of smallpox from different countries. In this chapter an account is given of the

activities of 9 international commissions which operated before the Consultation on the Worldwide Certification of Smallpox Eradication took place at WHO Headquarters in Geneva in October 1977. These include the 3 commissions which laid the foundation for all the others (see Chapter 24)—namely, those for South America, the first exploratory effort; Indonesia, a much more sophisticated procedure, but still in process of development; and western and central Africa, which set the pattern for the certification of many other countries in Africa and Asia from which smallpox had been eliminated several years earlier. The chapter closes with a brief de-

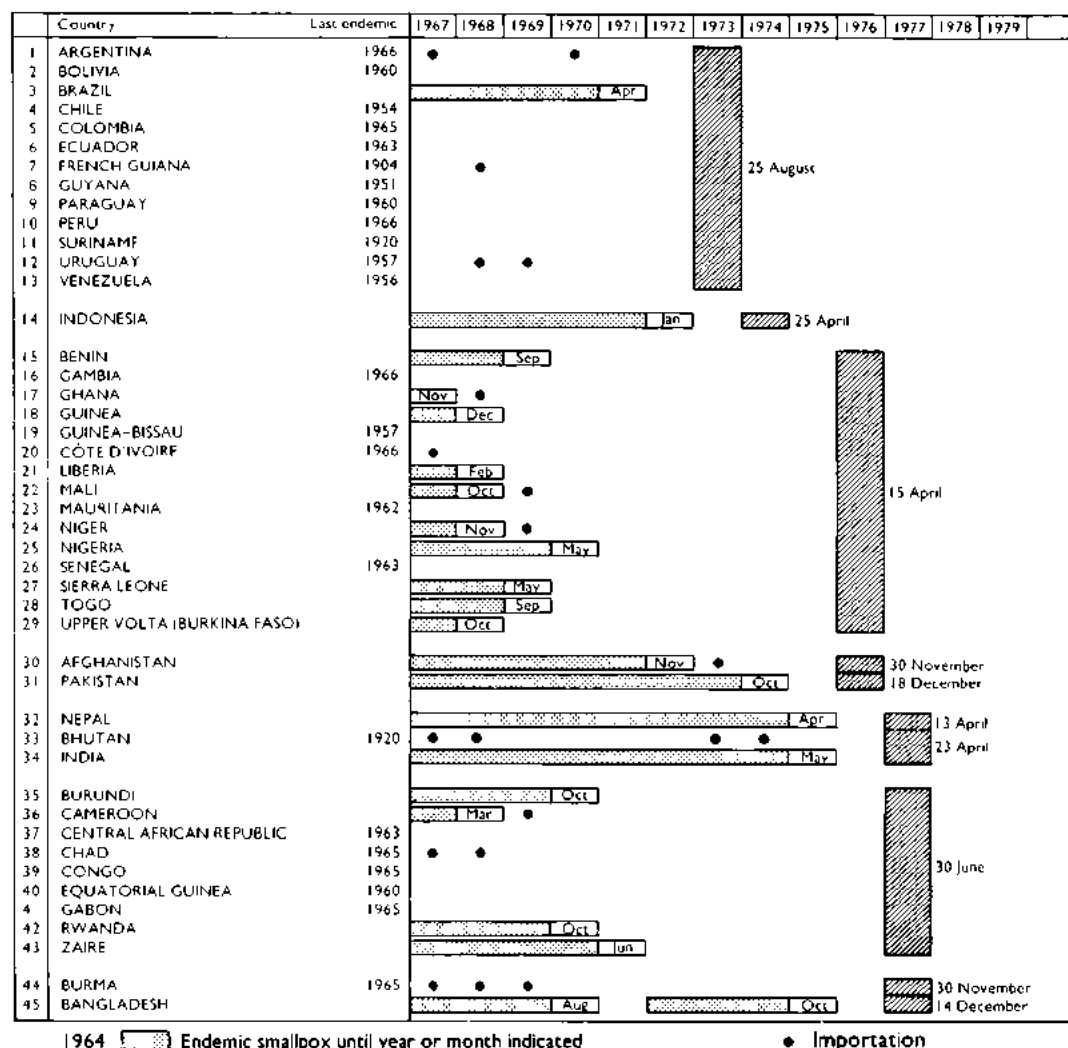

Fig. 25.1. Countries certified to be smallpox-free by international commissions operating between 1973 and 1977. The vertical boxes indicate the year in which the country was visited by an international commission; the dates on the right of these are those of the certification of the country or group of countries.

scription of the certification of the eradication of variola major from the world. This was carried out by the large international commissions which dealt first with Afghanistan and Pakistan in the west, and then with the principal and ancient home of variola major - India, Bangladesh and some of their small neighbours.

Fig. 25.1 shows the countries covered by these 9 international commissions, the month and year of the last cases in each country, and the dates of certification.

The special procedures adopted, the studies carried out and the factors which affected the decision by each of the international commissions to certify that eradication had been achieved are described in the sections which follow. Common to all countries, and of long standing, was the routine notification of a number of infectious diseases by hospitals and health centres, special attention being given to smallpox and the other diseases subject to the International Health Regulations (cholera, plague and yellow fever); all cases of these diseases had to be notified to WHO. Although the reporting of smallpox had been very incomplete when the Intensified Smallpox Eradication Programme began, the system then in place had served to detect and report cases in the endemic countries. During the course of the Intensified Programme, routine notification systems improved in all countries and, although they were not sufficiently sensitive to detect all the cases of smallpox that might have occurred, it was unlikely that any of them would fail to detect at least some of the numerous cases which would have had to occur if transmission was sustained over many years. The continuing absence of reports of cases of smallpox, often for a period of some years during which other diseases were being reported to WHO, increased confidence in the certification process, especially in countries in which certification was undertaken several years after the occurrence of the last known case of endemic smallpox.

## CERTIFICATION IN SOUTH AMERICA

The last case of smallpox in South America was reported from Brazil in April 1971; South America was certified free of smallpox in August 1973.

### Recent History of Smallpox

The history of smallpox in South America since the late 1950s has been described in Chapter 12. The essential features are summarized below as a background to the precertification activities and the recommendations of the Commission for the Assessment of the Smallpox Eradication Program in the Americas, which met in 1973.

After 1967, when the Intensified Smallpox Eradication Programme was initiated, only 3 countries in South America and the French Overseas Department of French Guiana reported cases of smallpox. The disease remained endemic in Brazil, which had long been reporting several thousand cases of variola minor annually, while Argentina, French Guiana, and Uruguay reported a few cases between 1967 and 1970, following importations from Brazil (Table 25.1). All the other South American countries had reported their last cases before 1967 (see Chapter 8, Fig. 8.6) and the last importation into the subcontinent from outside South America was believed to have occurred as long ago as 1920. Certification activities were therefore concentrated on Brazil and on adjacent countries in which importations from Brazil might have led to the establishment of new endemic foci.

### Precertification Activities

In April 1971, the month in which the last outbreak of smallpox occurred in Brazil, it was decided that surveillance should continue

Table 25.1. South America: number of reported cases of smallpox, 1966-1972

Country	1966	1967	1968	1969	1970	1971	1972
Argentina	21	30 <sup>a</sup>	0	0	24 <sup>a</sup>	0	0
Brazil	3 623	4 514	4 372	7 407	1 771	19	0
French Guiana	0	0	1 <sup>a</sup>	0	0	0	0
Peru	13	0	0	0	0	0	0
Uruguay	0	0	2 <sup>a</sup>	3 <sup>a</sup>	0	0	0

<sup>a</sup>Considered to be due to importation from Brazil.

in Brazil for 2 years after the occurrence of the last known case and that an assessment of the smallpox situation should then be made throughout South America (see Chapter 24). Over the next 2 years, country reports were prepared for submission to an independent assessment group by 11 countries (Argentina, Bolivia, Brazil, Colombia, Ecuador, Guyana, Paraguay, Peru, Suriname, Uruguay and Venezuela) and French Guiana; all of these except Brazil had been free of known endemic smallpox for at least 5 years. Chile was excluded because it had no common border with Brazil and, having a reasonably sophisticated health service infrastructure, had found no endemic smallpox to report since the early 1950s.

### Brazil

The vaccination campaign carried out between 1967 and 1971 had covered over 80% of the Brazilian population of 97 million. As has already been mentioned, the last case of smallpox occurred in April

1971, in Guanabara State, but the campaign was continued until the International Commission's visit in 1973. By 1971, epidemiological surveillance units had been established in 2904 of the 3951 *municípios* (73%), and formed an important reporting network for suspected cases, the proportion of *municípios* with such units rising to 89% in 1972 and 90% by June 1973 (Table 25.2).

In 1972, health personnel conducted special inquiries aimed at collecting rumours of smallpox cases throughout the country. They interviewed personnel working in government agencies, such as political and health officials, schoolteachers and pupils, and workers in factories and businesses. More than 300 000 persons were interviewed in areas in which the risk of unreported cases of smallpox was believed to be the greatest (Table 25.3). This survey found 96 suspected cases, but none of them proved to be smallpox.

During the course of the organized surveillance programme between January 1971 and June 1973, 1293 suspected cases of smallpox were investigated (Table 25.4). Specimens

<sup>a</sup> Including 19 confirmed cases from the last outbreak of smallpox in Brazil.

were collected for laboratory diagnosis from 792 of them; all gave negative results except the 19 specimens collected in Guanabara State during the last outbreak, which were positive. No evidence of smallpox transmission was found after April 1971.

### Argentina

The last case in Argentina occurred in April 1970, in an outbreak of 24 cases in Misiones Province, which borders on Brazil. This began with an importation from Brazil

and was contained by mass vaccination as soon as it was discovered. By the end of 1971 the vaccination campaign in the province had reached 84% of the population of 443 020 persons. During the summer of 1971 Dr Claudio Marcos da Silveira, a WHO consultant, visited Argentina to assess the smallpox situation. With Dr Juan José Hiriart, chief of the national smallpox eradication programme, he contacted schoolteachers, health officers and community leaders in areas in which cases of smallpox had been reported between 1965 and 1970, paying special attention to the community of Colonia Alicia, in which the 1970 outbreak had occurred. A survey in these areas showed that 88% of the 2819 schoolchildren examined had vaccination scars. Investigation of 26 cases of fever with rash led to the diagnosis of chickenpox in all of them. No cases of smallpox were found.

#### *Colombia*

The last cases of smallpox had occurred in Colombia in 1965. Between 1967 and 1972 more than 13 million of the 22 million people in the country were vaccinated, and a survey in 1970 found that 70% of the age group 0-4 years, 85% of the age-group 5-14 years and 77% of those aged 15 years and over had vaccination scars. Vaccination coverage was satisfactory except in 6 sparsely settled departments in the Amazon region. No evidence of recent smallpox was found during the vaccination scar survey.

In November 1971 a special survey was conducted in the Amazon basin in the Commissary of Vaupés (90 000 square kilometres), one of the more isolated areas, adjacent to the Brazilian Amazon basin. It was found that in the previous year, 8 cases of fever with rash had occurred in the San Jorge District on the bank of the Vaupés river opposite the town of Mitú. These had been diagnosed as smallpox in the hospital at Mitú, but the investigation revealed that 4 of them were in persons who had been previously vaccinated and that all were cases of chickenpox. A further search for cases of fever with rash found no evidence of smallpox in this area.

#### *French Guiana*

No cases of smallpox had been recorded in the files of the public health authorities of French Guiana since 1904. One case imported from Brazil into Cayenne had occurred in

1968 but it did not appear in the official records although it had been reported to WHO. Dr Marcos da Silveira visited the territory as a WHO consultant in 1971 and concluded that continued smallpox transmission was most unlikely for two reasons. First, the population was small (44 000), the reporting system was reasonably good and, although there was a risk of importation through persons entering illegally from Brazil, the areas adjacent to Brazil were so thinly populated that it was unlikely that an endemic focus could be established. Secondly, the vaccination programme was continuing and the records showed that in 1970 nearly half the children under 1 year of age had been vaccinated; this suggested that the coverage of the older age groups should have been reasonably good.

#### *Paraguay*

The last outbreak of 32 cases in Paraguay followed an importation from Brazil in 1965. In 1971 an investigation was conducted by a team of WHO operations officers and national personnel in the areas at highest risk, all of which bordered on Brazil. The survey team travelled 5000 kilometres, visited 88 localities, interviewed 125 health personnel and 451 teachers and educational personnel, and discovered 15 cases of exanthematous diseases, all of which had occurred during the previous 12 months. These cases and an additional 50 persons with a history of attacks of fever with rash were investigated, but no cases of smallpox were found.

Nor was evidence of smallpox found in a national survey of schoolchildren, conducted in 336 schools throughout the country in 1971. During the course of routine spraying operations in May of that year, the malaria control service personnel also conducted a search for smallpox cases among a population which comprised 4% of the national total, but found none. To determine the vaccination coverage, a special scar survey was conducted in May-June 1971 among 19 470 persons in the south of Paraguay. It was found that 78% had vaccination scars; the proportion was 43% in the age group 0-4 years and more than 82% in those aged over 4 years.

#### *Peru*

The 13 cases which occurred in Peru in 1966 were the last in a large outbreak of

variola minor that began in 1963, following an importation from Brazil. A vaccination campaign carried out between 1968 and 1970 resulted in a good coverage of the population, as was shown by a vaccination scar survey of 30 000 persons that was conducted in 1970. It was found that 82% of the age group 0-4 years, 92% of the age group 5-14 years and 91% of adults bore scars. The vaccination teams found no evidence of smallpox during the campaign.

#### *Uruguay*

The last importation of smallpox into Uruguay was recorded in 1969, before which there had been importations annually between 1960 and 1965 and again in 1968. Each case had been carefully investigated in order to determine the source of infection and each outbreak had been traced to a person exposed in Brazil. The prompt reporting and careful epidemiological investigations gave grounds for confidence that the health authorities would have detected and reported other cases had they occurred. In 1971 a small vaccination scar survey was conducted; of the 1029 persons examined, 98% had been vaccinated.

#### *Other countries*

Bolivia, Chile, Ecuador, Guyana, Suriname and Venezuela had also conducted good vaccination programmes (see Chapter 12), and the most recent cases in each country were associated with importations. Bolivia reported its last case in 1964, Chile in 1963, Ecuador in 1963, Guyana in 1951, Suriname in 1920, and Venezuela in 1962; indigenous transmission had been interrupted in most of these countries several years earlier (see Chapter 8, Fig. 8.6).

In 1971 special vaccination and search programmes were carried out in the Amazon basin areas of Bolivia, Ecuador and Venezuela, in parallel with those conducted in Brazil and Colombia. No cases of suspected smallpox were found.

### **Visit of the International Commission**

The Commission for the Assessment of the Smallpox Eradication Program in the Americas, as it was called, first met in Rio de Janeiro on 15 August 1973, and discussed the reports that had been prepared by each of the 11

countries and by French Guiana. The Commission was charged, as were all those that followed it, with the responsibility of reaching one of two possible conclusions: that it was satisfied that smallpox eradication had been achieved, or that it would be satisfied that smallpox eradication had been achieved if a specifically described set of activities were conducted and no further cases discovered.

The Commission split up into teams which visited several areas of epidemiological importance in Brazil. They participated in the epidemiological investigation of suspected cases of smallpox and observed the operation of the existing epidemiological surveillance system. The Commission held its final meeting in Brasilia on 25 August. As has been pointed out in Chapter 24, the constitution of this first international commission was not ideal, nor did it carry out its work with the same thoroughness as later international commissions.

The Commission reviewed the situation in the various countries. Its conclusions may be summarized as follows:

(1) Although the vaccination campaigns conducted in the 1960s throughout South America were in general satisfactory, protection was generally insufficient in children under 5 years of age and in areas to which access was difficult. The Brazilian campaign was regarded as notable for having reached high levels of vaccination coverage throughout the country and in all age groups.

(2) There was a need to improve the reporting system in certain areas. However, the Commission was impressed with the excellent epidemiological surveillance throughout Brazil, where there was a widespread network of reporting posts covering 90% of the *municípios* of the country.

(3) While the larger South American countries and Uruguay maintained services for the laboratory diagnosis of smallpox and, following the last reported case in April 1971, laboratory confirmation of the diagnosis of every suspected case was important, the quality of the laboratory work was not as satisfactory as might have been hoped. The Commission drew attention to certain deficiencies in the collection, packaging and shipment of specimens, which sometimes made laboratory diagnosis difficult. It also observed that there was no interchange of information between laboratories, even within the same country. Although the WHO

collaborating centre in Atlanta, USA, had agreed to test specimens, few specimens were submitted between 1967 and 1977 and most of them were from Brazil (Table 25.5).

(4) Although vaccine production in various countries in South America was sufficient to cover local needs, some countries continued to produce liquid vaccine intended for use wholly or in part in their respective jurisdictions. Even when it was freeze-dried, the quality was often not satisfactory; this applied, in particular, to the heat stability of egg vaccine produced in Brazil (see Chapter 12). Few laboratories regularly sent vaccine specimens for quality control to the WHO Reference Centre for Smallpox Vaccine for the Region of the Americas in Toronto, Canada.

Despite the deficiencies mentioned above, the Commission concluded that smallpox transmission had been interrupted in the region, but took a cautious approach to post-eradication policy, recommending that:

(1) Countries should continue to give due attention to reporting systems and to their improvement, particularly in areas in which reporting was weak, so that consistent information was immediately available on every suspected case.

(2) A sufficient number of adequately trained epidemiologists should be made available for epidemiological surveillance services, so that each case of suspected smallpox might be thoroughly investigated by a competent epidemiologist and specimens, taken under satisfactory conditions, sent to a laboratory.

(3) Smallpox having been eliminated from the Region of the Americas, and the laboratory investigation of every suspected case being of fundamental importance to epidemiological surveillance, the Pan American

Health Organization should stimulate the establishment of a system designed to ensure the technical proficiency of the laboratories performing smallpox diagnostic procedures.

(4) In order to ensure that the vaccines produced in the region were of high quality, samples of 3 consecutive lots of vaccine should be sent every 4 months to the reference laboratory for quality control tests.

In essence, the Commission recommended that vaccination and surveillance activities should be continued in much the same way as before eradication. Since it was agreed that there was little likelihood of importing smallpox from another continent, this recommendation reflects a certain lack of confidence in the decision that smallpox transmission had been interrupted. Such caution is understandable; this was the first time that smallpox eradication had been certified, and the disease had been endemic in South America for more than 400 years.

## CERTIFICATION IN INDONESIA

Although Indonesia was geographically close to the endemic countries of south-eastern Asia, no importation of smallpox had been recorded from them since 1949. It was therefore considered reasonable to undertake the certification of the eradication of smallpox in Indonesia in 1974, 2 years after the last known case.

## Recent History of Smallpox

Smallpox was reintroduced into Indonesia in 1947, but it remained confined to the larger islands of the western part of the archipelago

Table 25.5. Numbers of specimens from suspected cases of smallpox received by the WHO collaborating centre, Atlanta, USA, from countries in South America, 1967-1977<sup>a</sup>

<sup>a</sup> All negative for variola virus.

(see Chapter 13, Fig. 13.3). The numbers of cases in these islands between 1967 and 1973 are shown in Table 25.6. The last case of smallpox in the country occurred in January 1972, in a village some 30 kilometres from Jakarta, West Java.

### Precertification Activities

Smallpox surveillance continued until April 1974, when the International Commission visited Indonesia. In collaboration with national staff, WHO smallpox eradication programme staff—namely, Dr Giuseppe Cuboni (May 1971–October 1974) and Mr William Emmet (August 1970–July 1974)—continued to help with precertification surveillance.

In August 1973, Dr Paul Wehrle, a WHO consultant, visited Indonesia to review the progress of certification activities and to advise on other steps to be taken in order to demonstrate convincingly that eradication had been achieved. He visited 26 provinces in North Sumatra, South Sulawesi, West Java and West Kalimantan to assess surveillance activities, using as indices the regularity with which the weekly smallpox reports were submitted, the number of notifications and the number of laboratory samples collected and tested. He reported that he was personally convinced that smallpox transmission had been interrupted in Indonesia but recommended various measures to improve surveillance.

Neither the activities of the national eradication programme nor those of the International Commission subsequently covered all the thousands of small islands in the archipelago. After 1949, no smallpox cases had been reported from any of the islands east of Sulawesi and Nusa Tenggara, although authorities on these islands routinely reported

cases of other diseases. If smallpox had occurred there, rumours would have come to the notice of the health service. Experience in many islands in the South Pacific had shown that smallpox transmission could not be maintained on isolated oceanic islands because the populations were too small to provide a continuous supply of susceptible persons. The small islands of the Indonesian archipelago had apparently been free from smallpox for several decades, and the chance of continuing endemicity there was considered to be nil.

### Special searches

Between March and December 1972 visits to the villages in which cases of smallpox had occurred during the period 1970–1972 were carried out by surveillance teams, consisting of national, provincial and regency smallpox eradication programme staff, in 11 provinces of Java, Sulawesi and Sumatra (Fig. 25.2). The main purpose of these visits was to ensure that the recent smallpox outbreaks had been thoroughly contained. In addition, rumours about suspected cases in localities or areas in frequent contact with those affected were investigated. Other localities that were searched were those that did not report regularly, those that were seldom visited by health personnel, and those in which frequent staff changes suggested some weakness in the local health services.

During these special searches, 1352 villages were visited and the civil authorities, religious leaders and the security forces questioned, and inquiries were made at health centres and schools. Of 650 reports of cases of suspected smallpox discovered, 629 proved to be cases of chickenpox; none was smallpox. Approximately 180 laboratory specimens were collected and tested by Indonesian laboratories, all with negative results. The

special searches failed to elicit any evidence of the occurrence of smallpox after January 1972.

#### *Reward for smallpox detection*

In May 1972, immediately after the last known case has been detected, the Indonesian government offered a reward of 5000 rupiahs (US\$12) to any person reporting a case of smallpox which was confirmed by laboratory tests. A similar amount was to be given to the first health worker who investigated and confirmed the case. The reward was given wide publicity by health workers when talking to the public during field visits (see Chapter 10, Plate 10.8C) in the hope of urging people to reveal rather than hide any new case.

#### *Routine reporting of suspected cases*

The existing system for the routine weekly reporting of suspected smallpox cases was

strengthened. In 1972, roughly 20% of the expected number of weekly reports were submitted, whereas in 1974 the level had risen to 50% at both the regency and provincial levels. Between 1972 and 1974, 6186 cases of suspected smallpox were reported and 8505 cases investigated (Table 25.7), the latter number including additional suspected cases discovered during the investigations of the original cases. As usual, the disease most frequently mistaken for smallpox was chickenpox, which accounted for about 70% of the total suspected cases seen, other skin diseases (scabies, measles, impetigo and dermatitis) accounting for the remainder.

#### *Laboratory diagnosis*

After what was thought to be the last case of smallpox in Indonesia had been reported in 1972, the laboratory investigation of suspected smallpox became of vital importance. The number of specimens collected in various

Table 25.7. Indonesia: routine reporting of cases of suspected smallpox, May 1972–February 1974

Year	Number of suspected cases					Source of reports (%)			
	Reported	Total Investigated	Chicken-pox	Smallpox	Others	Health personnel	Civil authorities	Members of the public	Unspecified
1972	2 298	3 223	2 236	0	987	38	27	25	10
1973	3 067	4 175	2 781	0	1 394	38	31	18	13
1974	821	1 107	613	0	494	44	26	21	9
Total	6 186	8 505	5 630	0	2 875	-	-	-	-

geographical areas was considered to be an index of the sensitivity of the surveillance system. Laboratory tests (gel precipitation and virus isolation) were carried out locally at the Biofarma Virological Laboratory in Bandung or the Central Public Health Laboratory in Jakarta, but specimens considered to be of special importance were also investigated by the WHO collaborating centres. In spite of the time required for shipment and communications—from the field to Jakarta, then to Geneva, then to a collaborating centre in the USA or USSR, and back by the same route—the results of tests carried out at the collaborating centres were available to the field staff within 5 weeks of the specimen being collected in 1972 and within 4 weeks in 1973 and 1974.

In addition to collecting laboratory specimens from all suspected smallpox cases, from September 1972 onwards health personnel were instructed to collect specimens from clinically unequivocal chickenpox in persons over 14 years of age who had no evident vaccination scar and from persons who had become ill in an outbreak of chickenpox in which a death had occurred. This type of surveillance was introduced after the last smallpox outbreak, in which cases had been reported to resemble chickenpox.

Between 1971 and 1973, altogether 1758 specimens were tested (Table 25.8), none being found positive for smallpox after 1972. Since chickenpox virus did not grow on the chorioallantoic membrane, hundreds of specimens from chickenpox viruses might be examined with consistently negative results. To encourage the laboratory workers and to test the laboratories' ability to grow

poxviruses on the chorioallantoic membrane, samples were occasionally submitted from vaccinia lesions, from which vaccinia virus could be grown; this explains the positive results for vaccinia virus in 1972 and 1973 shown in Table 25.8.

#### *Local declaration of smallpox-free status*

The national programme director decided that the local authorities should be responsible for confirming that smallpox was no longer prevalent in the areas under their jurisdiction. A total of 12 provinces in Java, Sulawesi and Sumatra had been defined as areas of concern, since cases of smallpox had been reported from them after 1970. In these provinces, both the civil authorities and the health service representatives of every village or area were requested to sign a document declaring that that locality was free of smallpox. Before this document was signed, every village chief and his local medical staff were given 2 weeks in which to check the area carefully and report any suspected case to the nearest health centre. However, the signing of the statement did not remove the duty to report any suspected case. On the contrary, all those involved were informed about the dangers of importation and the need for vigilance. This process was started in April 1973 and concluded in April 1974, involving 12 of the 26 provinces, as already mentioned, 158 of the 288 regencies and municipalities, 1771 of the 3203 subdistricts and about 25 000 of the 46 396 villages (*desas*) in Java, Sulawesi and Sumatra—a formidable task that required considerable organizational effort and logistic support.

These precertification efforts drew attention to smallpox and increased awareness of the reward offered both to health workers and to the general public for the notification of a case that could be confirmed.

#### *Special survey in Kalimantan and Sulawesi*

The health services in Kalimantan and Sulawesi were less well developed than those in Java and Sumatra; both islands had recently experienced smallpox and both were difficult places in which to work. In February and March 1974 special searches for smallpox, involving pockmark and vaccination scar surveys in the age group 0-14 years, were therefore carried out in these islands. South Sulawesi, in which the last endemic cases had

Table 25.8. Indonesia: laboratory diagnosis of suspected cases of smallpox, 1971-1973<sup>a</sup>

Year	Number of specimens	Number positive for:	
		variola virus	vaccinia virus
1971	150	15	0
1972	1 009	12	1 <sup>b</sup>
1973	599	0	6 <sup>b</sup>
Total	1 758	27	7

<sup>a</sup> Biofarma, Bandung, tested 1479 specimens, the Central Public Health Laboratory, Jakarta, 247 specimens and WHO collaborating centres 32 specimens.

<sup>b</sup> From samples from vaccinia lesions, submitted as a means of checking the ability of the laboratory to grow poxviruses on the chorioallantoic membrane.

been reported, was not visited, since an intensive eradication programme had been conducted there, followed by intensive surveillance. Primary schools and health centres were visited in the towns and large villages of 7 provinces of Kalimantan and Sulawesi, and inquiries made about smallpox rumours. It was considered that the epidemiological situation in these towns and villages, which were located in coastal areas and on rivers and served as communication centres for remote areas, would reflect that in the inland part of the islands which, because of limitations of time, funds and manpower, could not be searched.

A total of 27 538 children aged 0-14 years were examined in 22 selected localities. No facial pockmarks were found in the age group 0-4 years, while there were 27 pockmarked children in the age group 5-14 years, none of whom had had smallpox during the previous 2 years. This strengthened confidence that both Kalimantan and the selected provinces of Sulawesi had been free of smallpox since 1970. Vaccination scars were found in 26% of

children in the age group 0-1 year, 58% in the age group 1-4 years, and 83% in the age group 5-14 years. These levels of vaccination coverage were not satisfactory but, in view of the low population density in these islands and their isolation from the main endemic areas of Java, it was thought likely that smallpox transmission there had been interrupted in 1969.

### Visit of the International Commission

On 15 April 1974, 26 months after the last case of smallpox had been reported from Indonesia, the International Commission for the Certification of Smallpox Eradication (Plate 25.1) met in Indonesia. Dr Wehrle, who was well informed about the activities that had been undertaken in Indonesia and was thus in a position to guide the deliberations of the Commission, acted as chairman. After some discussion among the other members of the Commission, Dr Julie Sulianti Saroso, Director-General for the Control and Pre-

WHO

**Plate 25.1.** Participants in the meeting of the International Commission for the Certification of Smallpox Eradication in Indonesia, 25 April 1975. *Left to right, front row: J.J. Dizon (Philippines), J. Sulianti Saroso (Indonesia), P.F. Wehrle (USA), A. Karyadi (Indonesia); middle row: B. Cantayuda (Indonesia), I. Tagaya (Japan), N.McK. Bennett (Australia), J.S. Keja (WHO).* The names of the Commission members are in bold type.

vention of Communicable Diseases in the Indonesian Ministry of Health, was included as a member. This arrangement might be thought to have reduced the objectivity of the Commission's assessment but, on the other hand, her presence provided additional assurance that no areas of the country would be barred to members of the Commission (see Chapter 24). After the first meeting in Jakarta, the members of the Commission, accompanied by programme staff, left for the areas judged most likely to harbour smallpox cases—namely, Jakarta, North Sumatra, South Sulawesi and West Java, which were visited during a period of 2 weeks (Fig. 25.3). In their field work, the members concentrated on assessing the extent and sensitivity of the surveillance activities and reporting system, as well as on examining health records and interrogating health service staff and the public. They visited as many localities as possible, searching for patients suffering from fever with rash, whom they examined to ensure that they did not have smallpox. The Commission then held its final meeting in Jakarta on 24 and 25 April 1974. Having concluded that there was no evidence that smallpox had occurred in Indonesia since January 1972 and that surveillance activities appeared to have been adequate to identify cases had they occurred, it approved the certification of the eradication of smallpox in Indonesia as a whole.

Because of the continuing high incidence of smallpox in the Indian subcontinent and

the consequent risk of importations, the Commission strongly emphasized that "continuing vigilant surveillance and evaluation are necessary for all persons with illnesses suspected as smallpox", and recommended that "primary vaccination of infants and children against smallpox should be continued until global eradication of smallpox has been achieved".

### CERTIFICATION IN AFRICA SOUTH OF THE SAHARA

The organization of certification in Africa south of the Sahara constituted a special challenge for a number of reasons. The region contained 42 countries which had previously been endemic, or whose neighbours had previously been endemic, and had become smallpox-free between 1967 and 1977 (Fig. 25.4). Communication within and between many of these countries was difficult, and the health service infrastructure in most of them was at a rudimentary stage of development. The certification programme was implemented by grouping countries together geographically and on the basis of similar histories of the elimination of smallpox. One such grouping, western Africa, comprising 15 countries, was the first in which the feasibility of certification of a regional group was tested (see Chapter 24); this was followed by the certification of 9 countries in central Africa.

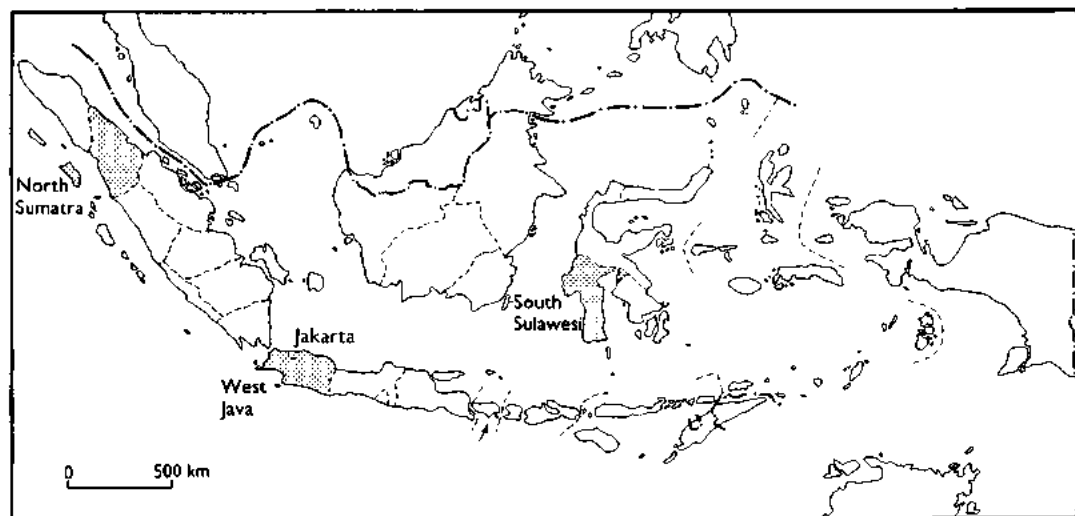

Fig. 25.3. Provinces of Indonesia (shaded) visited by members of the International Commission, 15-25 April 1974.

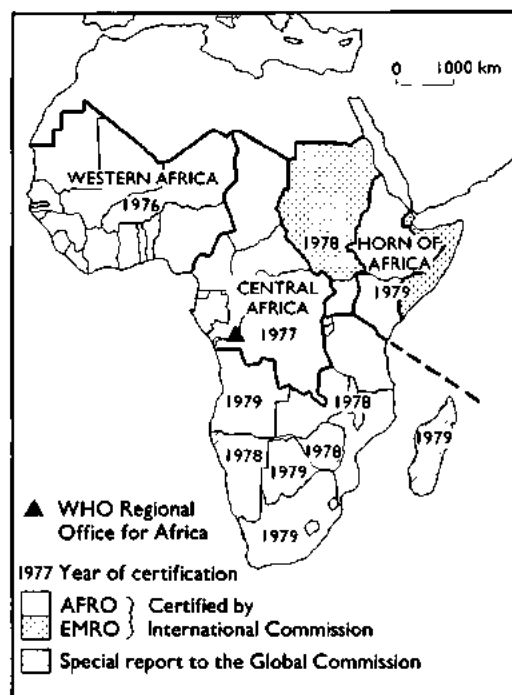

Fig. 25.4. Organization of certification in Africa south of the Sahara. A total of 42 countries were the subject of special certification procedures, 39 of them being in the WHO African Region and 3 (Djibouti, Somalia and Sudan) in the WHO Eastern Mediterranean Region. During 1976–1979 the certification programme was implemented by grouping countries together on the basis of geographical and epidemiological criteria.

Arrangements based on the epidemiological and political situation in another 14 countries in eastern and southern Africa led to their certification in 1978 and 1979, by a variety of methods (see Chapter 26). The 4 remaining countries in the Horn of Africa, as the last group, were eventually certified by international commissions in October 1979 (see Chapter 27).

### WESTERN AFRICA

In western Africa, 15 countries—Benin, Côte d'Ivoire, Gambia, Ghana, Guinea, Guinea-Bissau, Liberia, Mali, Mauritania, Niger, Nigeria, Senegal, Sierra Leone, Togo and Upper Volta (now Burkina Faso) (Fig. 25.5)—shared many features which made it logical to group them for the certification of smallpox eradication.

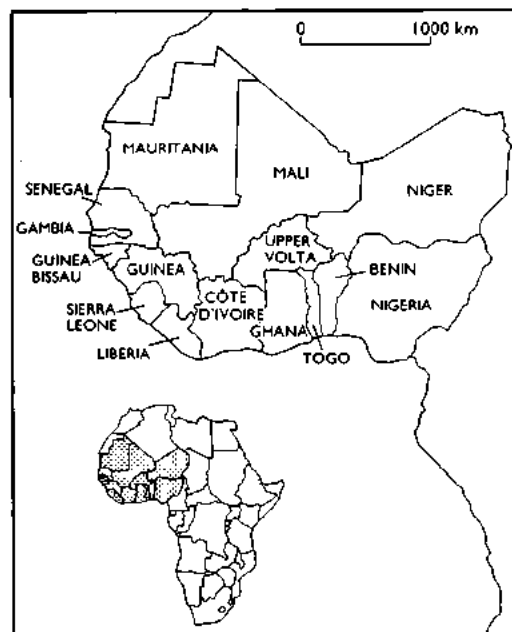

Fig. 25.5. The 15 countries of western Africa which were certified free of endemic smallpox by the International Commission in April 1976. Upper Volta is now Burkina Faso.

As has been described in Chapter 17, smallpox eradication and measles control programmes had been carried out in the region with United States support, and the last known outbreak of endemic smallpox had occurred in April 1970. Intensive surveillance had continued, with bilateral assistance, for more than 2 years thereafter, but both surveillance and the extent of vaccination had declined sharply after the assistance ceased. By 1976, when the International Commission for the Certification of Smallpox Eradication was scheduled to visit the region, the staff who had worked in the campaign had become involved in other activities or gone elsewhere, records were scattered or lost and smallpox surveillance activities had diminished. Because smallpox had been absent from these countries for more than 5 years, and because health services in western Africa were much less well developed than those in South America and Indonesia, it was decided that the surveys and documentation required before the Commission's visit could be—and, indeed, would have to be—simpler and adapted to the local situation.

### Recent History of Smallpox

The eradication campaign in these countries has been described in Chapter 17. Data on the numbers of cases reported between 1966 and 1971 are shown in Table 25.9. Unlike certain other regions of Africa, western Africa had experienced only variola major, usually associated with a somewhat lower case-fatality rate than in the Indian subcontinent. Hence facial pockmark surveys provided a valuable means of assessing the past prevalence of the disease.

Variolation had formerly been widely practised in many countries in the region (Herbert, 1975), but in the 1960s it was observed only in a few localized areas, the last being in Dahomey (Benin) in 1969.

### Preparations for Certification

#### *Planning meeting, 3-6 February 1975*

In order to plan a strategy for the certification of smallpox eradication in Africa, a meeting was held at the WHO Regional Office for Africa in Brazzaville, Congo, from 3 to 6 February 1975. It was attended by Dr Celal Algan, Regional Adviser on Communicable Diseases, Arita from the Smallpox Eradication unit at WHO Headquarters, and Dr Wehrle, the WHO consultant mentioned earlier in this chapter who had assisted with the planning of certification activities in Indonesia, together with other WHO staff.

The meeting agreed with the proposal that certification should start with the 15 countries of western Africa, since importations

were very unlikely from Ethiopia, the only African country in which smallpox was then still endemic, as it was 1500 kilometres away and there was little communication between the two areas.

Decisions were reached on 3 matters: local funding, coordination of precertification activities and the preparation of country reports. For most countries, WHO agreed to provide funds to cover the local travelling expenses (living allowances, petrol and oil) of mobile teams carrying out pockmark surveys. The other matters required continuing attention, as described below.

#### *Coordination of precertification activities*

During 1975-1976 the WHO Regional Office for Africa had medical epidemiologists stationed in Brazzaville (Dr Ziaul Islam), Côte d'Ivoire (Dr Alexander Dobrescu, Dr André Delas), and Nigeria (Dr Leva A. Arevshatian) to assist in epidemiological surveillance in western Africa. To coordinate the activities, Arita travelled throughout the area twice in 1975. During these trips a detailed manual describing how to carry out a pockmark survey was prepared and various technical and administrative problems were solved in discussions with the WHO epidemiologists and national health staff. At the request of WHO, Dr Joel G. Breman, at that time an epidemiologist from the United States Center for Disease Control working for the Organisation de Coordination et de Coopération pour la Lutte contre les Grandes Endémies en Afrique de l'Ouest (OCCGE), also assisted in promoting prep-

<sup>b</sup> Portuguese Guinea until 1974.

<sup>c</sup> Now Burkina Faso.

arations in the OCCGE countries (Benin, Côte d'Ivoire, Mauritania, Niger, Senegal, Togo, and Upper Volta).

#### *Preparation of country reports*

In preparation for certification, each country was requested to provide, by the end of 1975, a formal country report documenting its smallpox eradication activities. Simple forms indicating the essential information required in the country report were distributed to all countries in the region in order to ensure uniformity in the documentation.

*Pockmark surveys.* Each of the countries was asked to organize pockmark surveys, carried out by special mobile teams operating for a period of 3-6 months. In order to simplify the

operation, towns or villages with more than about 1000 inhabitants were to be selected, based on the demographic data for the country concerned, so that their combined population should be not less than 20% of the total population. In these localities, schools, maternal and child health clinics, hospitals and markets were to be visited to search for facial pockmarks in infants and children up to 15 years of age. Special instructions and forms describing how to select localities, how to conduct pockmark surveys and how to record the results were distributed to all the countries by WHO.

The surveys were completed by December 1975, and reports on the results became available in January 1976. As has already been mentioned, the localities surveyed were limited to large towns or villages, well distributed

#### **Rationale for Pockmark Surveys in Western Africa**

The rationale for conducting large-scale pockmark surveys in the countries of western Africa was outlined in 1976 in a memorandum by Henderson. In it, he discussed how best to provide the information that would allow an international commission to decide whether smallpox transmission had ceased in countries in which the last reported case had occurred several years earlier, and in which intensive smallpox surveillance had ceased some 5 years before the visit by the commission. He suggested that extensive facial pockmark surveys might be useful:

"For smallpox to have persisted during the past 4 years in the 15-country African area concerned, it is evident from what we know of the epidemiology of the disease that a large number of people living in a fairly large geographical area would have had to experience illness if the chain of transmission were to persist. Two-thirds of those afflicted would still bear facial scars of the disease and most of these would be children. To determine whether or not smallpox had been absent from this area, over this extended period, it would seem to me that one might examine a large number of children in many different geographical areas. If none had facial scars resembling those caused by smallpox which had been acquired during the past 4 years, one should be able to state with reasonable confidence that continuing smallpox transmission had not occurred in the 15-country area.

"To conduct such a study on a village-by-village basis would be ideal but expensive in terms of time and manpower. Practically, however, one might undertake to examine all those up to perhaps 15 years of age who attend school. Such an examination could be quickly performed as the children are already assembled in groups and children from a wide geographical area would be represented. Some, undoubtedly, would bear facial scars acquired more than 4 years before. If these children were identified, enumerated and the information confirmed that the disease had indeed been acquired more than 4 years previously, this would be further evidence that facial scars would be identified if present.

"An assessment which would be much simpler than this would be hard to visualize. The difficulties in undertaking such an appraisal would need to be carefully considered and, as well, whether the evidence obtained (with such other data as might be compiled) would be sufficient to permit an international commission to endorse the view that smallpox had been eliminated from the 15-country area concerned."

throughout the country; small villages in remote and inaccessible areas were excluded because of the considerable time and resources that would have been required to reach them. The view was taken, and later accepted by the International Commission, that, if smallpox transmission had continued, the disease should have reached larger towns or villages at some time between 1971 and 1976, and pockmarked persons would have been seen there.

The selection of localities can be illustrated by the arrangements made in Nigeria, the largest and most populous country in the region and the major focus of smallpox during the eradication campaign (see Chapter 17). Table 25.10 shows the numbers of localities of various sizes selected for assessment and their total population; 9.5% of all inhabited

localities were surveyed, accounting for 37.7% of the total population of Nigeria. The localities were widely scattered throughout the country; their geographical distribution is shown in Fig. 25.6.

The field survey teams in the 15 countries examined a total of 6.5 million persons, made up of 1.6 million preschool children, 3.7 million primary-school children and 1.2 million over primary-school age, representing over 25% of schoolchildren up to 13 years of age and 5% of the total population of 122.4 million of western Africa (Table 25.11).

<sup>c</sup> Formerly Dahomey.

<sup>d</sup> Now Burkina Faso.

During these surveys, over 8000 individuals with facial pockmarks were identified among persons of primary-school age or older. Almost all of them had had smallpox before 1971; in a few, the lesions were due to other causes. In no case did the interrogation reveal a missed case of smallpox. There were no pockmarks among children below the age of 6 years.

*Suspected smallpox cases.* During the pockmark surveys the teams visited hospitals and dispensaries to ascertain whether there were any rumours of smallpox. If suspected cases were seen, specimens were taken for laboratory examination.

Between 1972 and 1976, 11 countries in the region had reported 127 cases of suspected smallpox, none of which was confirmed on investigation. In contrast to the extensive laboratory investigations in Indonesia (see Table 25.8), between 1971 and 1973, only 75 laboratory specimens had been sent to the WHO collaborating centre in Atlanta, USA, from western Africa (Table 25.12), because no special searches for suspected smallpox had been carried out. None of these specimens yielded variola virus, but in 41 of them herpesvirus particles were seen by electron microscopy.

### Visit of the International Commission

The International Commission met first in Abidjan, Côte d'Ivoire, from 23 to 26 March 1976, to review the country reports and survey data. Western Africa was divided into 5 zones, each of which was visited by a team consisting of members of the International Commission accompanied by temporary advisers and WHO personnel. Each team visited all the countries in the zone allocated to it. Their investigations included a review of additional records available at the national and local levels, interviews with personnel involved in various aspects of the programme, and visits to selected localities to verify the sensitivity and effectiveness of the smallpox surveillance effort, including verification of the recently completed facial pockmark surveys. The Commission finally met in Brazzaville from 12 to 15 April to consider the additional data obtained during the field visits.

A number of questions had been clarified during the field visits. Overall, the reports showed that in all the countries excellent vaccination and surveillance programmes had been conducted in 1967–1972 and good pockmark surveys in 1975. Although the surveillance and reporting systems in most countries were better than those in operation before the eradication programme began in 1967, no cases of smallpox had been reported from any country in the region since 1970. In addition, between 1970 and 1976, 8 cases of human monkeypox had been discovered in Côte d'Ivoire, Liberia, Nigeria and Sierra Leone. The disease resembled smallpox clinically but not in its epidemiology (see Chapter 29). The fact that these cases, which had occurred in remote areas, had been discovered was evidence of the efficiency of the surveillance systems.

The long period (6 years) of apparent freedom from smallpox in western Africa predisposed the Commission to believe that transmission had been interrupted, a view that was strongly supported by the fact that the very extensive pockmark survey had produced no evidence of smallpox transmission after 1971.

The Commission concluded that there was no evidence that smallpox had occurred in the 15 countries of western Africa since 1970, and certified the region as being free of smallpox. Bearing in mind that smallpox transmission persisted in Ethiopia, however, it recom-

mended that vaccination programmes should continue, particularly for preschool children. Continued careful surveillance, and especially the reporting and investigation of all chickenpox outbreaks in which deaths had occurred, was most important, so as to make certain that these outbreaks were not caused by smallpox introduced from an endemic area or by monkeypox or related viruses.

### CENTRAL AFRICA

Following the certification of smallpox eradication in the 15 countries of western Africa, preparations for certification were organized over the period June 1976 to June 1977 for 9 countries of central Africa: Burundi, Cameroon, Central African Republic, Chad, Congo, Equatorial Guinea, Gabon, Rwanda and Zaire (Fig. 25.7). Apart from forming a geographical unit, these countries shared several features which made it reasonable to group them together for certification. As in western Africa, the USA had supported a smallpox eradication and measles control programme in certain countries in the region between 1967 and 1972—namely, Cameroon, the Central African Republic, Chad, the Congo, Equatorial Guinea and Gabon. WHO-assisted smallpox eradication programmes had been in operation in Burundi, Rwanda and Zaire. Zaire, the largest of these 9 countries, with a population of 26 million in 1977 (half the entire population of the group), developed a WHO-assisted smallpox eradication programme in 1967. The last case of smallpox in Zaire—the last in this group of countries—was recorded in June 1971, and active surveillance was continued throughout Zaire, with WHO support, until 1977.

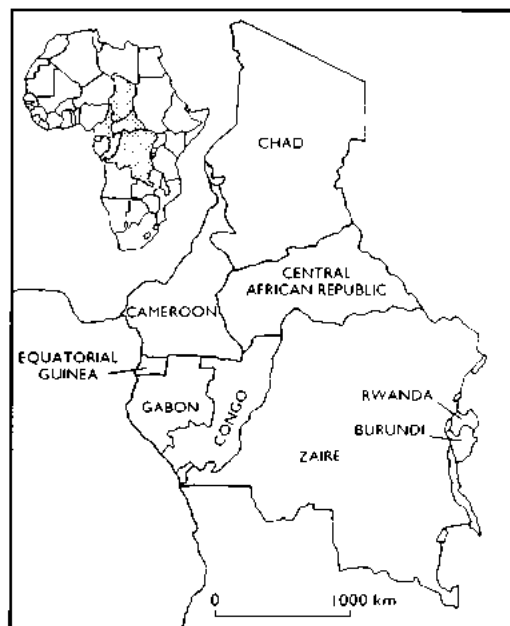

Fig. 25.7. The 9 countries of central Africa certified free of endemic smallpox by the International Commission in June 1977.

French was the official language of 8 of these central African countries,<sup>1</sup> making it much easier to prepare documentation and arrange meetings than in western Africa, in which both English and French had to be used.

### Recent History of Smallpox

Smallpox had been endemic in most of these countries until the mid-1960s (Table 25.13). In the 1950s and early 1960s outbreaks

<sup>1</sup> Both English and French are official languages in Cameroon, while Spanish is that of Equatorial Guinea.

of both variola major and variola minor had been reported in Zaire, but there was some uncertainty about the validity of diagnoses (see Chapter 18). After 1962 the usual African type of variola major was the only variety of smallpox seen in all these countries, hence pockmark surveys promised to be as useful here as they had proved to be in western Africa.

## Preparations for Certification

### *Coordination of precertification activities*

It had been agreed that, in preparing for certification, activities similar to those found satisfactory in western Africa should be carried out—namely, the preparation of standardized, relatively simple country reports and the organization of pockmark surveys. Work on the preparation of country reports was begun in July 1976, and from 11 to 15 October 1976 a coordination meeting was held in Brazzaville to discuss the preliminary results and the procedures to be followed.

Representatives from the 9 countries, together with consultants and staff from the WHO Smallpox Eradication unit, attended the meeting, at which the preliminary country reports submitted by country representatives and the methodology of pockmark surveys were reviewed. WHO agreed to provide funds to cover the local travelling expenses (living allowances, petrol and oil) of mobile teams carrying out pockmark surveys. June 1977 was agreed as the date for the visit of the International Commission, since it was thought that by then all country reports

and pockmark surveys would have been completed.

Dr Islam provided each country with the statistical data available at the WHO Regional Office for Africa in Brazzaville. Since such data were not always easily available in the countries concerned, this greatly facilitated the preparation of the country reports.

Zaire was treated differently from the other countries. A detailed country report was requested, but it was agreed that pockmark surveys would be carried out only in the epidemiologically critical border areas, since country-wide active surveillance for smallpox had continued ever since the discovery of the last case in 1971. A special monkeypox survey was planned as part of the precertification activities, since monkeypox was clinically indistinguishable from smallpox. It consisted of a search for unreported human monkeypox cases or smallpox-like disease in areas within a 25-kilometre radius of villages in which human monkeypox cases had occurred in the past.

### *Preparation of the country reports*

**Pockmark surveys.** The field survey teams examined over 1.3 million persons, constituting 2.5% of the total population of the central African countries (Table 25.14). In all, 1.5% of preschool children and 8.8% of schoolchildren were examined. Pockmarks were found in 1420 schoolchildren and 146 adults, but there were none in the preschool age group (0-5 years).

Table 25.14. Central Africa: results of pockmark surveys, 1976-1977

Country	Population (millions) <sup>a</sup>	Number of persons examined			
		Total	Preschool age <sup>b</sup>	School age <sup>b</sup>	Adults <sup>b</sup>
Burundi	3.9	77 574	6 000 (0)	71 574 (18)	0
Cameroon	7.9	326 819	14 428 (0)	312 391 (6)	0
Central African Republic	2.1	119 277	17 920 (0)	101 357 (0)	0

Rwanda	4.7	81 149	9 109 (0)	72 040 (6)	0
Zaire	26.2	396 440	48 491 (0)	264 738 (1 238)	83 211 (144)
Total	51.7	1 333 543	122 841 (0)	1 108 463 (1 420)	102 239 (146)

<sup>a</sup> Population data for 1977 from United Nations (1985).

<sup>b</sup> Number of persons with facial pockmarks shown in parentheses.

<sup>c</sup> .. = data not recorded.

**Laboratory diagnosis.** The number of specimens sent to WHO collaborating centres between 1972 and 1976 varied from one country to another (Table 25.15), but the great majority were collected in Zaire. Variola virus was not found in any of the 748 specimens examined, but 14 specimens collected in Zaire were found to contain monkeypox virus.

### Visit of the International Commission

The first meeting of the Commission was held in Brazzaville from 6 to 8 June 1977. Subsequently, the Commission formed 6 teams, which between them visited all the countries in the region. The type of investigation undertaken by these teams can be illustrated by the report of the subgroup that visited Zaire, which consisted of Dr A. M'Baye and Dr J. G. Breman, Commission members from Senegal and the USA respectively, assisted by Dr Pierre Ziegler and Dr Edilberto Zanotto, former WHO staff from the Zaire smallpox eradication programme.

Between 8 and 26 June 1977 the subgroup reviewed the country report, the results of the facial pockmark survey and the special report on monkeypox, and visited 28 zones in Zaire, including some in each of the 9 regions of the country. In addition, the detailed locally prepared survey reports were reviewed and 57 government and private health units visited.

The subgroup also visited 35 schools, 16 markets and a refugee camp in order to examine preschool children and school-

children for facial pockmarks caused by smallpox. In all, 13 450 children were examined or re-examined. No child of less than 7 years of age showed facial pockmarks attributable to smallpox. The vaccination coverage of schoolchildren was satisfactory (about 90%). Investigations by national staff of 33 suspected cases were reviewed by the subgroup; no evidence of recent smallpox was found.

The Commission met again in Brazzaville from 28 to 30 June 1977 and, after discussing the findings of the field visits, concluded that there was no evidence that smallpox had occurred in any of the 9 countries of central Africa since August 1971. Specific questions by the teams about variolation and laboratory stocks of variola virus elicited the information that variolation was not practised in any of these countries, nor were stocks of variola virus held in their laboratories. Since smallpox was still endemic in Somalia, the Commission recommended that careful surveillance should be continued and vaccination campaigns maintained, particularly for preschool children, in all countries until such time as the global eradication of smallpox could be certified. The Commission also recommended that active surveillance of human monkeypox should be maintained.

### CERTIFICATION IN AFGHANISTAN AND PAKISTAN

Afghanistan and Pakistan, which share a border of about 1000 kilometres, were the first countries on the Asian mainland from which the eradication of smallpox was certified. In both, the national eradication programmes were started in 1967; the last cases were recorded in 1973 and 1974 respectively. The geographical features and ethnic make-up of the border areas were similar on both sides of the frontier and cases had been imported across it into Afghanistan. Smallpox was still endemic in India in 1975, but Pakistan's long border with India was closed, and population movements across it were infrequent.

In contrast to the situation in western and central Africa, in which the last outbreaks occurred in 1970 and 1971 respectively and many countries in both regions had been free of endemic smallpox for several years previously, the disease had been endemic in Afghanistan and Pakistan recently enough for the intensified surveillance of the later

Table 25.15. Central Africa: number of specimens from suspected cases of smallpox submitted to WHO collaborating centres for laboratory diagnosis, 1972-1976

stages of the eradication programme to be carried over into the preparations for certification. For this reason reliance was placed on active surveillance and searches, rather than on the pockmark surveys used in Africa. The same international commission dealt with the certification in both countries in the latter part of 1976, a few months after the certification of western Africa and before that of central Africa.

## AFGHANISTAN

The last case in Afghanistan was recorded in July 1973 but, because of the prevalence of smallpox in neighbouring Pakistan and the concern that foci of unreported smallpox might remain in remote areas of the country, surveillance was reinforced. Dr Arcot G. Rangaraj, a WHO epidemiologist, remained in Afghanistan until certification had been completed. Dr Abdul Mohammad Daramanger of the Ministry of Health played an

important role in the 12-member National Committee for Smallpox Eradication, which took responsibility for the preparations for certification.

Analysis of the sources of outbreaks occurring during the last 4 years of endemic smallpox (Table 25.16) showed the need to pay particular attention, in the precertification surveillance activities, to variolation and nomadic groups.

## Precertification Activities

### *Surveillance: 1973-1975*

For operational purposes, Afghanistan was divided into 4 zones (see Chapter 14, Fig. 14.3) and subsequently into 3 zones—namely, Kabul, Kandahar and Kunduz (see Fig. 25.8). To search for and investigate suspected cases, special surveillance teams had continued work after the last case, 3 teams being located in the Kabul zone, 3 in the Kandahar zone, and 1 in the Kunduz zone. Special surveys

Table 25.16. Afghanistan: outbreaks of smallpox, 1970-1973

Source of outbreaks	1970		1971		1972		1973	
	Number	%	Number	%	Number	%	Number	%

Total number of outbreaks	83		107		44		3	
Total number of cases	1 044		736		236		25	

were organized in areas in which smallpox outbreaks had occurred after 1967, either through natural transmission or through variolation, and in border provinces, as well as those in which nomads were concentrated during the summer. During the period 1974-1975, 255 of the 327 administrative units of the country (78%) were visited by surveillance teams, but no new focus of smallpox infection, indigenous or imported, was detected.

About 700 villages were identified in which variolation had been practised in the past, and 90 of them—those in which it had been performed most recently—were repeatedly checked and visited. Neither practising variolators nor fresh variolation scars were detected. In addition, 155 nomad encampments were visited and searched in the Kabul, Kunduz and Kandahar zones, with the same result.

#### *Special active search in 1976*

A special active search for suspected cases in rural areas was carried out in 1976 by 7 smallpox surveillance teams and 15 combined BCG/smallpox vaccination teams. These teams checked all villages with more than 250 persons and, regardless of the size of the population, all previously affected villages and those in which variolation had been practised. The teams moved from province to province, arranging their operations according to the climatic and geographical conditions of the area to be searched. Of the 28 provinces, 22 were covered, an average of 6-8 villages being visited daily by each team. Over 8000 villages were searched, accounting for 93% of the villages with a population of more than 250 in the country. Teams also

visited and interviewed people in 1548 markets, 2100 tea-shops and 1192 schools throughout the country. Two months later, the same areas were visited by assessment teams which interviewed villagers and assessed the work of the search teams in 10% of these villages. It was found that many villagers had seen searchers and 88% knew where and to whom to report suspected cases. During the search, 262 suspected cases of smallpox were found; 135 (51%) of them proved to be cases of chickenpox and 110 (42%) measles; the remaining 17 were cases of other skin diseases such as eczema, scabies and dermatitis.

A special pockmark survey was conducted among the 0-4-year-old children of nomads. Altogether, 5107 of these children were examined in 8 provinces inhabited by nomads during the summer. Only 2 children with pockmarks were found, both of whom had contracted smallpox more than 3 years earlier while travelling between Pakistan and Afghanistan.

#### *Collaboration of the malaria control programme in the active search*

During the period April-June 1976, in addition to the active searches carried out by surveillance and mobile vaccination teams, about 1000 malaria control programme workers carried out another search in densely populated areas below an elevation of 2000 metres—i.e., where malaria transmission occurred. About 13 000 villages were visited, 680 000 households searched and about 3 million people interviewed. Not only were suspicious cases detected, none of which proved to be smallpox, but the search also assisted in increasing the awareness of the

population of the need to notify suspected smallpox cases.

### *Hospital searches*

In April-June 1976, local health staff in provincial hospitals, maternal and child health clinics and basic health centres made inquiries among visiting outpatients about any suspected cases present in their home villages or towns. The search resulted in the detection of 223 suspected cases; 55% proved to be measles and 28% chickenpox, the remaining 17% including a variety of skin diseases. Furthermore, staff of the provincial hospitals participated in searches in the towns and in villages located within a 5-kilometre radius. As an incentive, from 1976 onwards a reward of 3000 afghanis (US\$51) was offered for every report of a confirmed case of smallpox. Despite these activities, no evidence was found of recent smallpox. All the results indicated that smallpox had not been present in the country during the previous 3 years.

### *Variolation*

From the inception of the Intensified Smallpox Eradication Programme in Afghanistan, there was concern that variolators, who were especially active in the central and eastern parts of the country, might play an important role in smallpox transmission (see Chapter 14). In fact, 47 of the 237 outbreaks recorded between 1970 and 1973 could be specifically attributed to variolation (see Table 25.16). The last known variolation in Afghanistan was recorded in Dand Area of Kandahar Province in April 1976. However, none of the 57 children

variolated at that time had developed any skin lesions at all. Evidently the variolation material used contained no viable virus.

Throughout the eradication programme, staff had attempted to identify variolators, to learn about their practices, and to persuade them to give up variolation. Whenever possible, they collected specimens of variolation material so that it could be assayed for the presence of viable virus. Also, intensive efforts were made to educate the population about the dangers of variolation and to vaccinate systematically throughout the country in order to demonstrate that vaccination was available to all. These measures proved to be remarkably successful.

The remaining question of concern was whether it might be possible for a variolator to retain over a period of many years scabs containing viable variola virus of sufficiently high titre to permit successful variolation. Variolators who were interviewed in 1976 claimed to have given up the practice during the previous few years, partly because villagers had gradually ceased to seek their services and partly because of pressure from the government. Most variolators asserted that the variolation material they had used was not effective for more than 1 or, at most, 2 years. Since smallpox had been absent from the country during the past 2 years it was therefore thought unlikely that many persons would attempt variolation because of the lack of effective material. Of 9 specimens collected from variolators in Afghanistan from 1969 to 1976, none had yielded viable virus since 1970, when smallpox was still endemic (Table 25.17).

Specimens were studied by virus isolation and electron microscopy, virus being isolated

Table 25.17. Afghanistan: results of laboratory tests of specimens of variolation material obtained from variolators

Age of specimen	Type of material	Date collected	Results	
			Poxvirus particles by electron microscopy <sup>a</sup>	Virus isolation
?	Fluid	March 1969	..	+

?	Scabs	April 1976	+	-
6 years	Powder	May 1976	+	-
6 years	Scabs	May 1976	+	-
10 years	Scabs	May 1976	+	-

<sup>a</sup> Virus particles may be visualized by electron microscopy, even though not viable; .. = not done.

from 4 of them. Three of the isolations were made from relatively fresh samples, 2 being between 4 and 9 months old; the third was fluid and would have dried up if it had been stored for more than 12 months. The fact that, as Table 25.17 shows, in 4 other specimens numerous poxvirus particles could be demonstrated by electron microscopic examination but virus could not be isolated suggested that viable variola virus probably did not survive under normal conditions for more than 2 years, or perhaps a much shorter period.

However, in the cold mountainous regions of Afghanistan in particular, the possibility could not entirely be ignored that one or more variolators might have been able to preserve for years material which contained variola virus with a titre sufficient to produce successful takes. One variolator from Kunar Province had stated in an interview that he (as well as a colleague in Peshawar, Pakistan) usually preserved scabs in a screw-capped container which was buried in the ground in a mountainous area. He considered this material to be effective for up to 10 years. On further questioning, however, he stated that fresh material had to be added to the basic stock each year.

### Visit of the International Commission

The International Commission visited Afghanistan between 22 and 29 November 1976. After a preliminary meeting in Kabul, members of the Commission visited the 3 national smallpox eradication programme zones (Fig. 25.8) before their final meeting in Kabul.

They found that good records had been kept of smallpox control activities and that the work of the zonal smallpox eradication programme staff was of a high order. The basic health service units played a valuable role in investigating suspected cases of smallpox, but the recording and reporting of such activities was not standardized and was deficient in places. A number of recent suspected cases were reinvestigated and confirmed not to have been smallpox. The pockmark surveys of children showed that no outbreaks had occurred after the time when the zone concerned had been considered to be free from smallpox. No pockmarks were observed in children under the age of 5 years.

Checks for vaccination scars confirmed that a very high proportion of children had

Fig. 25.8. Provinces (shaded) in the 3 zones of Afghanistan visited by members of the International Commission in November 1976.

been vaccinated, as reported by national smallpox eradication programme staff, the major exceptions being in some nomad camps, where small groups of families were found to have been missed. The Commission teams were most impressed with the level of knowledge about smallpox, vaccination and the importance of reporting suspected cases found among all sections of the community. Knowledge of the reward was widespread in most of the provinces visited.

Variolation scars, which could be distinguished from scars due to vaccination since they were on the wrists or the dorsum of the forearm (see Chapter 14), were common in adults, but there was no evidence of recent variolation other than that reported in Kandahar Province in April 1976, already mentioned.

The Commission certified smallpox eradication in Afghanistan on 30 November 1976, noting that the energetic and thorough surveillance activities carried out since 1972 would have been adequate to disclose cases of smallpox if they had occurred. Because some parts of Asia had still to be certified and the transmission of smallpox was still occurring in the Horn of Africa, the Commission recommended that surveillance and vaccination should be continued until global eradication had been certified.

As far as variolation was concerned, the Commission concluded that, although it was unlikely that scabs containing live virus remained in the possession of variolators, the possibility that variolation might cause future outbreaks could not be completely

excluded. The Commission was concerned about this prospect and strongly recommended that vigilance should be maintained. In fact, a further 3 years elapsed after the Commission's visit before the Global Commission finalized its report, during which time no case of smallpox was reported. This strengthened the belief that viable variola virus did not survive in variolators' material.

## PAKISTAN

The last case of smallpox occurred in Pakistan in September 1974 (Table 25.18) and eradication was certified in December 1976.

### Precertification Activities

As in Afghanistan, surveillance measures were further strengthened in all provinces after eradication because of the concern that foci of unreported cases might still be present, especially in "problem areas"—i.e., areas not easily accessible for geographical or political reasons. First priority was given to active search operations.

#### *Country-wide searches*

In 1975 several active searches were carried out by various categories of staff: vaccinators, searchers, malaria and family planning field staff and other health workers. In 1976 the searches were extended to the entire country, covering the majority of the rural areas. Three complete search operations were carried out in January, May and August 1975, usually for periods of 2 weeks each, although this was extended to 21 working days in many areas to ensure the best results. After each search operation, an independent assessment was made by the district and provincial sur-

veillance teams, covering 5% of randomly selected localities in the territory already searched.

Similar search operations were carried out in urban areas throughout Pakistan. The administrative organization and health services available in the towns made it necessary for these searches to be carried out independently of those in rural areas. In general, municipal vaccinators and general health staff, supported by volunteers, carried out house-to-house searches in all slums, sweeper colonies (areas to which migrants normally went), other poor socio-economic areas, cantonment areas, railway settlements, the areas in which the last 20 outbreaks of smallpox had occurred, and the areas on the outskirts of towns in which nomads usually settled. In June and July 1976 a special all-Pakistan urban search was carried out in towns with a population of over 50 000, and in all district headquarter towns, regardless of their size. An intensified health education campaign was also carried out in these towns before search activities commenced.

#### *Searches in problem areas*

Provincial and district surveillance teams, assisted by local health staff, organized repeated special searches in the problem areas previously mentioned, which might not have been properly searched in the course of eradication activities. As a rule, randomly selected villages and settlements in such areas were visited, and information on the occurrence of smallpox cases during the past 2 years was collected and checked; in addition, vaccination scar and pockmark surveys were carried out among children under 5 years of age.

These special searches were intensified during the first half of 1976, when particular attention was paid to parts of Azad Kashmir, the areas bordering on China, remote areas of Baluchistan inhabited by nomads, mountain-

Table 25.18. Pakistan: number of reported cases of smallpox, 1970-75, by province or area

Province or area	1970	1971	1972	1973	1974	1975
Azad Kashmir	0	0	0	0	9	0
Baluchistan	80	291	559	801	202	0
North-west Frontier	525	2 654	1 338	194	163	0
Punjab	1 480	2 036	1 495	415	1 503	0
Sind	1 107	827	3 661	7 846	5 982	0
Total	3 192	5 808	7 053	9 258	7 859	0

ous parts of Punjab, flood-affected riverine areas in Sind and on the border with India, and the Thar desert (Fig. 25.9).

*Active searches in areas in which the last outbreaks occurred*

During 1975 and again in March–April 1976, a special team composed of the most competent vaccinators, sanitary inspectors and health assistants, together with district surveillance teams, visited the areas in which the last 20 outbreaks had occurred in each district, reassessed the previous reporting, case-finding and containment activities, and carried out an active case search in all the localities within a 5-mile (8-kilometre) radius of the previously affected areas. Pockmark surveys were conducted on a large scale, particularly among children under 2 years of age, in an effort to find undisclosed cases, but none was found in that age group.

In the districts in which smallpox incidence had been low and the number of outbreaks small, all localities which had had smallpox outbreaks in 1974 were visited and the epidemiological situation rechecked in an effort to disclose possible continuing transmission.

To assess surveillance independently, surveillance teams from one province visited another province or area for periods varying

from a few weeks to 2 months. Thus, in 1976, provincial and district teams from Punjab assessed the efficacy of the programme operations in Azad Kashmir, Baluchistan, and North-west Frontier Province; Sind provincial and district teams did the same in Baluchistan and Punjab.

*Rewards*

The cash reward offered for finding smallpox cases was increased from 100 rupees (US\$10) to 200 rupees, and in July 1975 to 500 rupees. The reward was publicized as widely as possible by means of the radio, press and wall posters in order to encourage the public to report suspected cases.

In November 1975, the following new system of rewards was introduced:

- 1000 rupees to anyone who reported an active case of smallpox;

- 100 rupees to any health worker who discovered a child with facial pockmarks that originated from a smallpox-like disease which had occurred after October 1974;

- 1 rupee to search workers for every chickenpox case visited and recorded during the all-Pakistan search operation in January 1976.

The participation of the local administrative authorities was sought. A special postcard, signed by the Deputy Commissioner, was sent to each *numberdar* (village leader), asking him to question, within a week, all the inhabitants of his village as to the presence of smallpox cases and, if any existed, to report them immediately to the district authorities.

*Results*

As a result of all these activities, 49 874 cases of fever with rash were detected, reported and investigated by November 1976. The reporting of cases of chickenpox during the search periods was encouraged (Table 25.19), on the assumption that a surveillance system sufficiently sensitive to detect them would almost certainly detect smallpox outbreaks. Altogether, 27 703 chickenpox cases were reported. Laboratory specimens were collected from 157 cases in which the diagnosis was in doubt and tested by WHO collaborating centres for the presence of variola virus, with negative results. No focus of smallpox infection, indigenous or imported, nor any recent case of smallpox was detected. All the information obtained in

Fig. 25.9. "Problem areas" in Pakistan (shaded), in which special searches were carried out during pre-certification activities in 1976.

Table 25.19. Pakistan: number of cases of fever with rash investigated and number of cases of chickenpox reported between October 1974 and September 1976, by province or area

Province or area	Number of cases of fever with rash	Number of cases of chickenpox
Azad Kashmir and northern areas	608	524
Baluchistan	242	184
North-west Frontier	6 878	3 196
Punjab	31 267	16 658
Sind	10 979	7 141
Total	49 874	27 703

1975-1976 served to confirm that the disease had not been present in the country since October 1974.

#### Variolation

Variolation had been practised in Pakistan both in North-west Frontier Province and to a lesser extent in Punjab, but on nothing like the scale found in Afghanistan. Material was collected from several variolators during 1975. In 1976, local health staff throughout the country were asked to inquire about variolations performed in the last 12-18 months, to visit the areas concerned, and to try to locate the variolators and collect variolation material from them. Examination of 11 specimens by electron microscopy revealed poxvirus particles in 9, none of which yielded viable virus (Table 25.20). One specimen collected in 1975 showed numerous

herpesvirus particles, suggesting that a professional variolator, desperate to find a smallpox patient from whom he could replenish his material, took specimens from a chickenpox patient, either deliberately or after misdiagnosis.

#### Visit of the International Commission

The International Commission for the Certification of Smallpox Eradication in Afghanistan was also responsible for certification in Pakistan. It travelled to Islamabad after completing its visit to Afghanistan, and remained in Pakistan from 6 to 18 December 1976, members visiting 37 of the 71 districts or agencies in the country (Fig. 25.10).

#### Field visits

Evidence of the recent occurrence of smallpox was sought by means of pockmark surveys, especially among children, and by questioning people. A number of recent suspected cases were reinvestigated and confirmed not to have been smallpox. The areas selected for special searches included some of those in which smallpox had occurred late in 1974. Scar surveys were carried out to assess vaccination coverage and the extent of variolation. Where possible, known variolators were traced and interviewed and sites of outbreaks due to variolation were revisited. Inquiries were made among different sections of the population to determine the extent of

their knowledge of smallpox and of the reward offered for its detection.

#### *Results of searches*

The Commission's teams found pockmarks in 99 out of more than 7000 children under

the age of 15 (1.4%). Only 5 children under 5 years of age were found to have pockmarks; all were recorded cases from outbreaks which had occurred before October 1974. No undisclosed outbreaks were discovered during the Commission's surveys. A substantial number of recent outbreaks were reinvestigated and details of the cases verified in the records. No missed cases were discovered. The checks for vaccination scars showed that a very high coverage had been achieved among adults and older children, somewhat less satisfactory levels being found in some areas among children under 5 years of age.

The evidence of variolation scars in adults confirmed that this practice had been common many years previously in parts of Baluchistan, in certain of the tribal areas of North-west Frontier Province and in a few communities in other provinces. Variolation scars were seen in children in 2 of the areas associated with documented episodes in 1974 but, despite careful searches, not in children elsewhere. Ten former variolators were interviewed. They stated that variolation material did not remain potent for more than a year at the most and that the practice had been abandoned. Signs advertising the reward for

reporting smallpox were seen in many of the places visited and, although their distribution was uneven, knowledge of the reward was widespread.

### Conclusions

The Commission concluded that the smallpox eradication programme had achieved its goal in October 1974 and that there had been no smallpox transmission in Pakistan since that time. Although population movements across the long border between Pakistan and India were very limited, the Commission recommended that primary vaccination should be continued at least until the whole of Asia had been certified to be free of smallpox.

### CERTIFICATION IN THE REST OF THE INDIAN SUBCONTINENT AND BURMA

Bangladesh, Bhutan, Burma, India and Nepal, contiguous countries in a vast area

(Fig. 25.11) in which smallpox had been endemic for centuries, with frequent transmission across the international boundaries, were dealt with next. The last case of smallpox in India was reported in May 1975. Nepal and Bhutan experienced a number of importations from northern India as late as 1974 and 1975. In Bangladesh, freed from smallpox in 1971, major epidemics developed from 1972 onwards as a consequence of importations from West Bengal and Bihar. The last outbreaks of smallpox in Burma occurred in 1969, when an importation from Bangladesh resulted in 68 cases. Thus, in these 5 countries, continuing freedom from the disease depended very much on whether the adjacent country was smallpox-free. Because of India's large size and vast population, the smallpox situation in that country greatly influenced that in the others. Bhutan recorded its last smallpox case in February 1974, Nepal in April 1975 and India in May 1975 (Table 25.21). For certification purposes, these 3 countries were treated as a group and certified by international commissions in April 1977. Bangladesh recorded its last case in October

Table 25.21. Number of reported cases of smallpox in 4 countries of the Indian subcontinent and Burma, 1967-1976

Country	1967	1968	1969	1970	1971	1972	1973	1974	1975	1976

1975 and was certified in December 1977. Because of its contiguity, Burma was certified together with Bangladesh.

was discussed at an informal workshop held in Kathmandu, Nepal, from 29 January to 2 February 1977 (Plate 25.6).

## INDIA, NEPAL AND BHUTAN

### India

The last case of smallpox in India occurred in May 1975 and the country was certified to be free of smallpox in April 1977. Precertification activities were recognized as an essential follow-up to eradication, and WHO support in terms of personnel and funds (provided by Sweden) was continued. About 60 epidemiologists (20 international and 40 national) participated in the 2-year preparation for certification, a detailed account of which is given in Basu et al. (1979). Ježek, Dr Lev Khodakevich and Dr Nicholas Ward were responsible for coordinating the activities on behalf of WHO. At the national level, Dr R. N. Basu took full responsibility for certification preparations. Detailed planning

### *Precertification activities*

A thorough programme was undertaken, consisting of the following components: intensified surveillance for cases of fever with rash, active searches for possible cases of smallpox, laboratory testing of suspected cases of smallpox, and finally a comprehensive assessment of all this work by a national assessment commission.

*Surveillance of outbreaks of fever with rash.* A system for the surveillance of all cases of fever associated with a rash was introduced throughout India in January 1976. This required each health worker to report all such cases, as well as cases of and deaths from chickenpox, in addition to all cases suspected of being smallpox. Special registers for cases of fever with rash were established at each basic reporting unit—namely, 5323 primary health centres, 1005 municipal health offices, 1050

Breach (WHO), H.D. Mehta (WHO), A.M. Monnier (WHO), A.M. Scardaci (WHO), J.S. Friedman (WHO).

selected hospitals and 797 other peripheral notification posts, as well as 428 smallpox eradication programme offices based in district and state health establishments.

*Active search operations.* Active search operations, initiated as part of the eradication campaign in the autumn of 1973 (see Chapter 15), continued throughout the period from May 1975, when the last case was discovered in India, until April 1977, when the International Commission visited the country. The frequency of these active search operations is shown in Fig. 25.12.

Compared with the searches in 1973 and 1974 during the eradication programme, those carried out in 1975 and 1976 were both much more extensive and more intensive, and included 3 country-wide searches conducted in the autumn of 1975, the spring of 1976 and the autumn of 1976. These involved some 110 million households in more than half a million villages and 2600 urban areas. The major national search operations aimed at recording not only suspected cases of smallpox, but also any cases of fever with rash,

including chickenpox, measles and certain skin diseases. In addition, individual states intermittently carried out their own searches. Diagnoses were verified only by higher-level health officers. A reward of 1000 rupees (US\$100), introduced in July 1975, was offered to both searchers and health officers and the general public, and provided a strong incentive for the searchers to discover cases of smallpox, if they did occur (Plate 25.7).

More than 95% of all the villages in India were searched during each country-wide search. No smallpox cases were found although tens of thousands of cases of chickenpox were seen. The results of the subsequent assessment of some 10% of the villages already searched indicate that about 70% of the families knew about the smallpox reward and where to report the disease should they find it. Fig. 25.13 shows the percentages of households assessed as having seen the searchers in each survey, by district. The coverage by searchers was good in the 1975 search and improved still further in those carried out in 1976 (Table 25.22).

Number of villages found searched	68 551	77 193	104 596
Percentage searched	95.8	94.5	97.0
Number of households questioned	1 950 613	1 867 594	3 051 753
Percentage that saw searchers	94.0	79.3	86.0
Percentage that knew of reward	73.0	80.4	83.0

During 1976, altogether 1 951 487 cases were recorded in the registers for cases of fever with rash, 60% of them following active searches, 36% following routine village visits by health staff, reports by members

of the public or through the secondary surveillance system, and 4% as a result of market searches. All cases were examined by experienced health supervisors and none was found to be smallpox. The data on cases

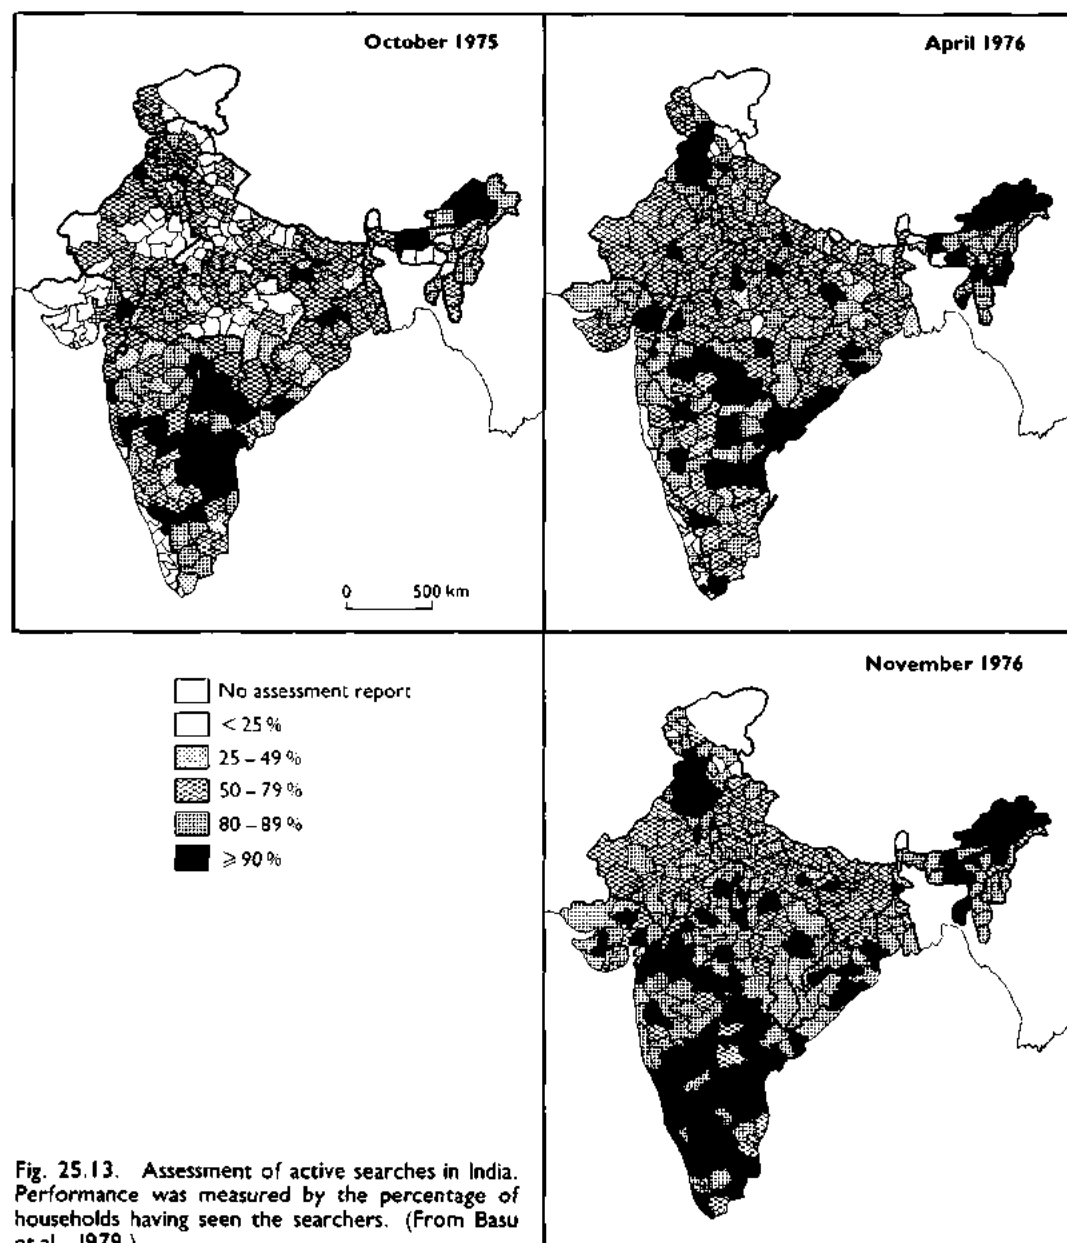

Fig. 25.13. Assessment of active searches in India. Performance was measured by the percentage of households having seen the searchers. (From Basu et al., 1979.)

entered in the registers are analysed in Table 25.23. In the same year, 519 651 localities in which these cases had occurred were visited by experienced senior health workers (37% of them by medical officers); in the first quarter of 1977, a further 322 526 localities were visited. The number and thoroughness of these investigations made it difficult to believe that smallpox could have persisted in India for 2 years without being detected.

Furthermore, 520 cases (102 suspected clinically to be smallpox and 418 deaths

in chickenpox outbreaks) were investigated in 1976 by experienced epidemiologists associated with the smallpox eradication programme (Ježek et al., 1978e) and 63% of the suspected smallpox cases were found to be due to chickenpox; none was smallpox.

As would be expected from the known seasonal incidence of the disease, by far the largest number of chickenpox outbreaks and cases occurred during the spring search (March-April 1976). In April 1976, a special study was carried out in the state of Kerala,

**Plate 25.7.** During the eradication programme in India the reward had gradually been increased from 10 to 100 rupees by the end of 1974. In July 1975, after smallpox was believed to have been eradicated from India, the reward was increased to 1000 rupees.

in which chickenpox deaths appeared to be unusually frequent, especially in adults (White, 1978). The investigation revealed that deaths attributed to chickenpox had been correctly diagnosed.

*Special searches.* In addition to the search operations just described, special searches were carried out in certain parts of the country which, for geographical reasons, were relatively inaccessible. These had posed problems for surveillance during the eradication campaign and required special attention during the precertification activities. First, surveillance activities were reinforced in the

Andaman and Nicobar Islands, Ladakh, Mizoram and Sikkim (Ježek & Kanth, 1978; Ježek et al., 1978b). Secondly, 353 sites of outbreaks at the end of 1974 and in 1975, dispersed over 55 districts located in 20 states or Union territories, were systematically reinvestigated in the latter part of 1976 (Ježek et al., 1978c). Investigations that included interviews with more than 128 000 households and the physical checking of over a quarter of a million persons yielded no evidence of hidden foci or missed outbreaks.

*Laboratory diagnosis.* During the Intensified Smallpox Eradication Programme, the diagnosis of smallpox had been confirmed by laboratory investigations mainly in suspected cases which had occurred in smallpox-free areas or areas of low incidence. The number of such investigations was substantially increased during the precertification activities, especially in the first quarter of 1977 (Table 25.24). From January 1976 onwards, special instructions were issued calling for specimens to be collected from a representative patient in every outbreak of suspected smallpox, from every chickenpox outbreak in which deaths occurred, and from every outbreak of a vesicular disease in which containment action was taken, even if by mistake. The last instruction was based on the fact that, before the active searches in 1973, vaccinators and health officials had occasionally concealed smallpox cases but carried out containment vaccination in the hope that the outbreak would subside.

In January 1975, the government of India arranged that the National Institute of Communicable Diseases should take sole responsibility for testing smallpox specimens from India; for this purpose, the Institute used both gel precipitation and virus isolation on the chorioallantoic membrane. The WHO collaborating centres in Atlanta and Moscow also tested many specimens and carried out electron microscopic examinations in addi-

1977 (end end of April)	1 385	0	..	..	..

<sup>a</sup> .. = data not recorded

tion to the other two methods. In principle, duplicate specimens were collected from each suspected case, one being tested by the National Institute of Communicable Diseases and the other by one of the WHO collaborating centres. For virus isolation, the results obtained were in full agreement. Laboratory investigations of 2025 specimens provided no evidence of smallpox in India during 1976 and 1977.

*Variolation and laboratory stocks.* In contrast to the situation in Afghanistan and Pakistan, variolation had not been a problem in India during the past few decades and no special inquiries were required. However, the situation with regard to laboratory stocks of variola virus was carefully evaluated and steps were taken in 1976 to ensure that all such material was destroyed.

#### *The national commission*

Before the International Commission's visit to India, scheduled for April 1977, the Indian government organized a national commission for the assessment of the smallpox eradication programme in India (Basu & Khodakevich, 1978a). This consisted of 32 members from the Union government of India and 12 state governments and from WHO (Plate 25.8). Both Dr Jan Kostrzewski (who was to be chairman of the International Commission shortly to be set up) and Arita also attended a coordination meeting of the national commission in January 1977, since successful certification of smallpox eradication in India by the International Commission was clearly an important milestone in certification in the world as a whole and thorough preparation was essential. The national assessment took place over the period from 13 December 1976 to 8 January 1977.

After a preliminary assessment of the situation, teams from the national commission investigated selected districts to assess their surveillance activities (Fig. 25.14). Although their observations might not be seen as completely impartial by observers outside India, the members of the national commission teams were extremely critical in assessing what had been accomplished since, if they failed to discover any deficiencies, they would be held responsible.

The national commission found no evidence of continuing smallpox transmission and India was considered ready to receive the International Commission in April 1977.

### Nepal

After what was regarded as the last case of smallpox in Nepal had been recorded in April 1975, surveillance was continued until the International Commission visited the country in April 1977. During the eradication programme, the country had been divided into 3 areas (see Chapter 15): (1) densely populated areas of low altitude adjacent to the Indian states of Uttar Pradesh and Bihar—i.e., the areas most vulnerable to smallpox importations; (2) high Himalayan mountainous areas with sparse populations and the least likely to experience importations; and (3) areas intermediate between (1) and (2). This subdivision was retained throughout the precertification surveillance period.

A similar surveillance strategy was adopted in all areas, active searches being carried out by means of house-to-house visits. The 3 main groups of surveillance workers were: smallpox eradication programme staff, malaria control staff, and health workers assigned to integrated health activities. Dr P. N. Shrestha, director of the national smallpox eradication programme, ensured

that the best use was made of available health workers in order to strengthen the surveillance activities. Mr Jay Friedman, a WHO technical officer who had been located in Nepal since 1972, remained there until the International Commission visited the country, and contributed to the success of the undertaking. No evidence of smallpox transmission was found at any time during the precertification activities.

In 1975 a special pockmark survey was conducted among 2350 Tibetan refugees; this found no evidence of smallpox transmission in Tibet (Xizang Autonomous Region) more recently than 1961 (see Chapter 27). This was extremely important, since little was known of the incidence of smallpox in China at that time. The survey indicated that the chance of smallpox importation from Tibet was extremely small.

### Bhutan

The last known case of smallpox in Bhutan occurred in February 1974, when 3 cases were introduced from Assam, India. In 1976 the

governments of Bhutan and India began discussions on the development of a special surveillance programme in preparation for certification. In August 1976 an Indian team, headed by Dr Basu, visited Bhutan to finalize the surveillance plan. An active search by means of house-to-house visits was carried out between September and December 1976, concentrated on the southern part of the country, where people moved freely across the border with India. A total of 23 surveillance workers visited about 800 villages; out of 45 000 persons seen, 11 were pockmarked. However, there was no indication of smallpox transmission after the last case in 1974.

### Visit of the International Commission

An International Commission consisting of 16 members from 16 countries visited Bhutan, India and Nepal in March-April 1977; groups of Commission members visited Bhutan from 28 to 30 March, Nepal from 6 to 13 April and India from 6 to 20 April. For political reasons, Bhutan and India were certified separately. Since at that time only

persons of Indian nationality were allowed to visit Bhutan, Lieutenant General R. S. Hoon, an epidemiologist serving in the Indian Defence Forces and a member of the International Commission, visited Bhutan together with Dr Basu, after which he participated in the investigation of the adjacent Indian state of Arunachal Pradesh.

All 16 members of the International Commission met first in New Delhi to assess the situation and plan field visits. During the field visits, each member was accompanied by national and WHO personnel who had either been members of the Indian national commission or were WHO epidemiologists who had worked in India during the precertification activities. In order to achieve maximum coverage, each member visited different areas in one or two states or union territories over a period of some 2 weeks (Fig. 25.15) before all the members of the Commission reassembled in New Delhi. Dr Kostrzewski with 2 members of the Commission and Ježek, who had been engaged in certification activities in India, visited Nepal, and then resumed their Indian field investigations. During the field visits, the Commission members concentrated on assessing the extent

and quality of the search and surveillance activities by examining records and interrogating several categories of staff at state, district, municipal, primary health centre and subcentre levels. They independently assessed the validity of statements about community awareness of smallpox by visiting villages, schools, urban areas, bazaars, places of pilgrimage and international ports. Brief reports were produced by the various Commission members or teams and these were discussed by the Commission at a plenary session from 21 to 22 April 1977.

In Nepal, 2 teams were formed, one covering the east and the other the west, special attention being paid to areas bordering on India. The members of the Commission were unable to visit the Tibetan border, but information collected from nearby mountainous areas indicated that Tibet was smallpox-free.

On 13 April 1977 Nepal was certified by the International Commission to be free of smallpox; this was followed, on 23 April, by the certification of Bhutan and India.

Plate 25.10. J. Kostrzewski, Chairman of the International Commission, presents the Commission's report to the Minister of Health and Family Welfare of India, Shri Raj Narain, on the occasion of the certification of eradication in that country on 23 April 1977. Shri Rajeshwar Prand, Secretary of the Ministry, is in the centre.

## BURMA AND BANGLADESH

### Burma

Indigenous transmission in Burma had been interrupted in 1966 by a systematic mass vaccination campaign that began in 1954 and was intensified in 1963, using locally produced vaccine of acceptable potency and heat stability. Smallpox was then reintroduced from the Chittagong Hill Tracts in Bangladesh (then East Pakistan) into the neighbouring Burmese state of Arakan, in which it caused an outbreak with 181 reported cases in 1968 and 68 in 1969. This was controlled by intensive vaccination. In 1970 a WHO team had declared Burma to be free of endemic smallpox, and no further cases had been reported since then.

Between 1968 and 1975, 51 suspected cases of smallpox were investigated by field staff and specimens examined for variola virus in the laboratory, with negative results. In 1976-1977 the government of Burma established 4 national assessment teams, which visited every state and division in Burma, carried out pockmark surveys among children in the age group 5-14 years, and assessed the vaccination coverage and evidence relating to cases of suspected smallpox. The reports of these national assessment teams provided the basis for the investigations by the International Commission. In order to coincide with certification in Bangladesh, the Commission's visit was arranged for November 1977.

### Bangladesh

The last case of smallpox in the Asian continent occurred in Bangladesh in October 1975; it was also the last case of endemic variola major in the world. As in India, the smallpox eradication programme retained its personnel and organization for the next 2

years in order to continue surveillance and determine whether the supposed last case really was the last one. Precertification activities in Bangladesh have been described by Joarder et al. (1980). Between October 1975 and May 1976, a large number of international and national staff were engaged in the search operations (Table 25.25). Among the many dedicated persons who contributed to the certification activities in Bangladesh, special mention may be made of Dr A. M. Mustaqul Huq, who had promoted the eradication programme since 1967, initially as programme manager and later as Director of Health Services (Preventive), and Dr Daniel Tarantola, a WHO epidemiologist, who stayed in Bangladesh until certification had been completed.

#### *Active searches*

Between October 1975 and October 1977 active country-wide searches for unreported cases, based on house-to-house visits, were organized on 8 occasions (Fig. 25.16). In each search, 50 000-60 000 health workers were mobilized. In the searches in December 1976-January 1977 and May-June 1977, deaths from chickenpox or measles were also investigated by interviewing a family member and/or taking specimens from other cases in the outbreak. A total of 56 deaths from chickenpox and 480 deaths from measles were investigated, as well as 63 deaths known only to have been caused by a disease in which there was fever with rash (Table 25.26). None of the fatal cases was due to smallpox.

After the search had been completed, the assessment team visited villages selected at random. They found that coverage by the search team varied between 78% and 87% (Table 25.26). More than 80% of the people interviewed knew about the smallpox reward.

Special searches were organized in the Chittagong Hill Tracts. The area was differ-

Table 25.25. Bangladesh: numbers of international and national epidemiologists engaged in surveillance, 1975-1977

Period	Number of WHO staff in Dhaka	Number of international field epidemiologists	Number of national epidemiologists	Total
July 1975	10	65	15	90
January 1976	7	21	20	48
July 1976	3	9	24	36
January 1977	3	7	32	42
July 1977	3	9	31	43

ent from other parts of Bangladesh in that the population was sparse, communications were poor and the health infrastructure was rudimentary. No evidence of smallpox was found.

#### *Surveillance in Dhaka and urban areas*

The active searches just described were carried out mainly in rural areas. However, it was in the major urban areas, including Dhaka in which housing was extremely congested and into and out of which tens of thousands of rural inhabitants flowed daily, that smallpox transmission had been maintained in the past, unknown to the central health services (see Chapter 16). In Bangladesh, moreover, the municipal health services were administratively independent of the district or regional health authorities, those responsible for smallpox eradication being no exception.

Surveillance in the municipalities therefore became an extremely important pre-certification operation. The methods employed were daily visits to infectious diseases hospitals and cemeteries to check on the causes of recent admissions, deaths and burials, and the use of surveillance teams, of which there were 2 in Dhaka and 1 in each of the other 5 major municipalities. They made regular visits to high-priority areas, including the bustees (the shanty towns, whose inhabitants were usually unfamiliar with the urban health facilities and, of course, with the reporting of information on rashes), areas of low literacy in which written publicity probably failed to reach the people, and places where the population congregated daily or intermittently in large numbers. House-to-house searches were conducted periodically in all municipalities, usually immediately after the national house-to-house searches in rural areas.

This schedule allowed surveillance teams and epidemiologists to devote additional time to the supervision and assessment of urban searches. None of these search activities disclosed evidence of continuing smallpox transmission after the case in October 1975.

#### *Pockmark survey*

A facial pockmark survey of 465 892 persons aged 0-19 years, based on 1550 sampling sites all over Bangladesh, was conducted in July-December 1976. None of the 939 persons with facial pockmarks who had

contracted smallpox after 1971 had been infected after 1975 (Table 25.27).

#### Laboratory diagnosis

Between January 1976 and November 1977, 2462 specimens were investigated by the smallpox diagnostic laboratory in the Institute of Public Health, Dhaka, and 698 were tested by WHO collaborating centres in Atlanta and Moscow (Table 25.28). In none was variola virus found, although vaccinia virus was recovered from vaccination scars and herpesvirus particles were seen in many of the specimens examined by electron microscopy in the WHO collaborating centres.

#### The national commission

A national commission of 52 members met in August 1977 to assess the smallpox eradication programme in Bangladesh. Teams from the national commission visited all districts, 54 subdivisions, 81 *thanas* and each of the 4 major municipalities in Bangladesh. After meeting again in Dhaka, the national commission expressed its satisfaction with the evidence that had been assembled to support the contention that there had been no smallpox transmission in Bangladesh after October 1975.

#### Visit of the International Commission

After a briefing session at the WHO Regional Office for South-East Asia, in New Delhi, a 9-member International Commission visited Burma from 21 to 30 November 1977 and Bangladesh from 1 to 14 December 1977. One representative from Burma and one from Bangladesh were included in the Commission because two politically disturbed areas—Chin State in Burma and the Chittagong Hill Tracts in Bangladesh, with a common border—could be visited only by nationals of the country concerned. In addition, the representative of each country was expected

to be particularly vigilant about the evidence of eradication in the other country.

### *Burma*

Field trips by Commission members covered an area with a population of more than 4 million in addition to the city of Rangoon (population 3.2 million). Together, International Commission members and national teams covered all the states and divisions of Burma. One of the main activities of the Commission members during their field visits was a pockmark survey, in which more than 58 000 persons were seen (5000 preschool children, 29 000 schoolchildren and 24 000 adults), among whom 399 pockmarked persons were identified. The majority of these (96.5%) had suffered from smallpox before 1963, the most recently infected being a person who had contracted the disease during the outbreak in Arakan in 1968. Extensive questioning found no evidence of the occurrence of smallpox in Burma after 1969.

Earlier in 1977 national assessment teams had examined 1.97 million children aged 5–

14 years without finding any with facial pockmarks. That the International Commission found 399 and the national commission none is explained in part by the fact that only 14 of those with facial pockmarks were under 14 years of age. It is also possible, however, that the definition of pockmarks was misunderstood during the national survey so that it did not give a truly representative picture of the prevalence of pockmarked persons.

Apart from this inconsistent result, the Commission was satisfied with the surveillance activities carried out by the Burmese health staff and found no evidence of smallpox transmission after 1970. Burma was certified to be free of smallpox.

### *Bangladesh*

After completing its work in Burma, the Commission met in Dhaka for 2 days at the beginning of December for briefing, then divided into 9 teams, each consisting of a Commission member, a WHO smallpox eradication programme officer, a national

epidemiologist and the local officers concerned. These teams travelled extensively throughout Bangladesh (Fig. 25.17) and made thorough investigations, particularly in vulnerable areas in which transmission of smallpox might be continuing. Extensive questioning revealed that the people's knowledge of the reward and of where to report suspected cases was very good. Pockmark surveys of some 50 000 persons under 20 years of age, of whom 2000 were less than 2 years old, found 575 pockmarked persons, none of whom had contracted smallpox later than 1975.

Scrutiny of documentation and supporting records showed that, with few exceptions, a high level of surveillance had been maintained by the national authorities throughout the period since the last known case.

The results of the field visits by the Commission were consistent with the national records, and on 14 December 1977 Bangladesh was certified to be free of smallpox. This action formally set the seal upon the end of endemic variola major in the world.

### CONCLUSIONS

These certification activities, which dealt with several of the former major endemic countries in the world, provided detailed information about the elimination of smallpox in the countries concerned and the methodologies for obtaining the data required by international commissions so that they could properly evaluate the likelihood that smallpox had been eliminated, both from countries in which it had recently been endemic and from those in which the last outbreak had occurred several years earlier. At the time the Consultation on the Worldwide Certification of Smallpox Eradication was held, in October 1977, preparations were well

Fig. 25.17. *Thanas* in Bangladesh (shaded) visited by members of the International Commission, 1-14 December 1977. (From Joarder et al., 1980.)

advanced for international commissions to visit other regions of Africa and Asia. It was on the basis of the knowledge and experience of certification gained between 1973 and 1977 that the Consultation was able to plan a logical series of operations that would ultimately provide the World Health Assembly with the information that would allow it to declare that smallpox had been eradicated from the world.

### INTRODUCTION

By June 1977 international commissions had already visited or were preparing to visit all the previously endemic countries and countries at special risk. However, as has been explained in Chapter 24, there was a need to determine what measures should be taken in order to certify that the transmission of smallpox had been interrupted for at least 2 years in other countries, in several of which

the staff of the WHO Smallpox Eradication Programme needed outside advice on how best to deal with the situation. In addition, advice on whether global eradication could be certified needed to be, and to be seen to be, independent of the special interests of WHO personnel who were intimately involved in the global eradication programme.

These problems could be solved by establishing a global commission of respected scientists which, as one of its functions, would

advise the staff of the WHO Smallpox Eradication unit as to what data should be collected, for clearly this was a matter of judgement. Eventually, when these experts were fully satisfied that global eradication had been achieved, this conclusion would have been reached, not by WHO itself, or on the basis of the reports of a series of international commissions each dealing with one or a few countries, but by an international group of senior scientists and administrators capable of taking a global view of the problem. For this reason, the Consultation on the Worldwide Certification of Smallpox Eradication was set up in October 1977 and subsequently converted into the Global Commission for the Certification of Smallpox Eradication. This chapter and the next deal with activities undertaken at the suggestion of the Consultation and the Global Commission throughout 1978 and 1979; it was hoped that these would provide data on which the Global Commission could ultimately base its opinion that the transmission of smallpox had been interrupted everywhere in the world.

In this chapter, various operations carried out in 29 countries situated in widely separated parts of Africa and Asia (Fig. 26.1) are described. Not all were certified by formal international commissions such as those referred to in Chapter 25; other procedures—a visit by a WHO-designated expert or consul-

tant and subsequent report, or the provision of a detailed country report—had to be used for some countries (Fig. 26.2).

In Africa, by mid-1977, formal certification had been successfully completed in 24 countries in western and central Africa (Chapter 25). At that time, smallpox was still occurring in Somalia, so that certification of the Horn of Africa lay in the future (Chapter 27). There remained 14 countries requiring certification, extending from the Sudan in the north to South Africa in the south, and from Angola in the west to Madagascar in the east. The strategy of certification by international commissions, as recommended by the 1977 Consultation, was followed for 10 of them (Fig. 26.2, No. 1–10), but for political and logistic reasons it was not possible to follow the Consultation's recommendations for South Africa, Namibia or Southern Rhodesia (Fig. 26.2, No. 13–15). Instead, certification by the Global Commission was based on reports prepared by Global Commission members and WHO consultants after visits arranged by the Smallpox Eradication unit. As recommended by the Consultation, eradication in Madagascar was certified by the Global Commission after receipt of a detailed country report, followed up by a visit by a WHO staff member.

For 11 countries in south-western Asia, certification by various procedures was recommended. Democratic Yemen, Yemen, Iraq and the Syrian Arab Republic (Fig. 26.2, No. 11, 12, 18 and 19) were visited by international commissions. Iran was visited by experts and certified by the Global Commission on the basis of their reports. The 6 Arab countries of the Gulf area (Fig. 26.2, No. 20–25) were required to submit a country report. At their request a more searching inquiry was made; each country carried out an intensive surveillance programme designed and supervised by a WHO epidemiologist.

For 5 countries in eastern Asia, the Consultation had recommended special certification activities. China, because of its vast size and population and its lack of contact with WHO for many years, required the special measures described in Chapter 27. There remained Thailand and the war-torn countries of Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam. The fact that there had never been a WHO-sponsored smallpox eradication programme in the 3 last-mentioned countries, and that their health systems had been compromised by prolonged

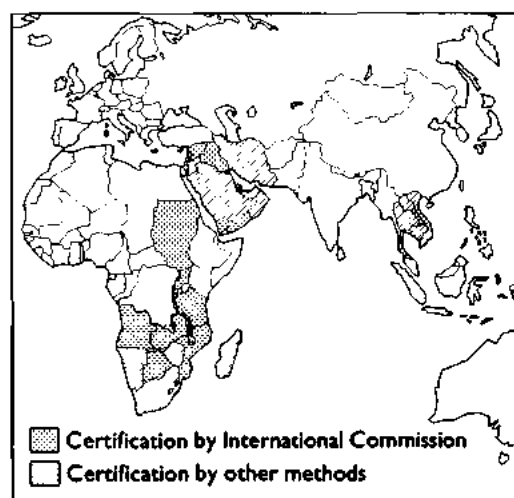

Fig. 26.1. The 29 countries of Asia and Africa (including Lesotho and Swaziland) in which certification was carried out in 1978 or 1979 by international commissions, by visits by a WHO-designated expert or by the provision of a detailed country report (see Fig. 26.2).

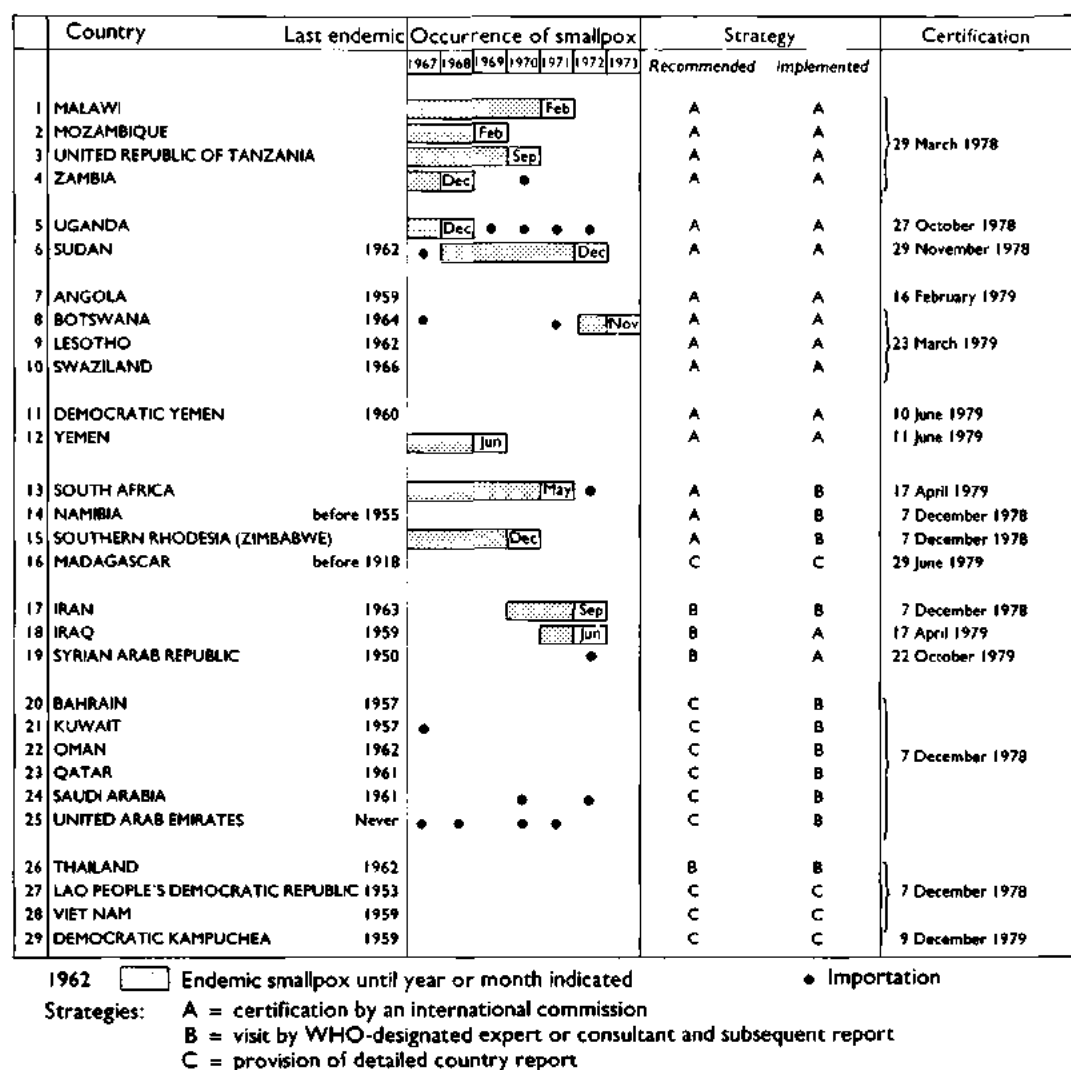

Fig. 26.2. Year of the last case of endemic smallpox and of importations of smallpox, and dates of certification of 14 countries in Africa and 15 countries in Asia according to the strategies recommended by the Consultation on the Worldwide Certification of Smallpox Eradication, October 1977, and as implemented.

warfare, made it difficult to collect data or arrange visits by WHO consultants or staff members. Thailand was visited by a member of the Global Commission; for the other countries reliance had to be placed on reports compiled from a variety of sources.

In this chapter, the certification of 14 countries in Africa is first described, then that of the 11 countries in south-western Asia and finally that of Thailand, Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam. All these operations were undertaken while, at the same time, the most intensive search activities of the whole eradication programme were being carried out in the Horn of Africa. The operations mounted to certify eradication in Ethiopia, Somalia, Djibouti and Kenya, and in China, are described in Chapter 27.

## SOUTHERN AFRICA

The progress of certification in the 12 countries of southern Africa (Angola, Botswana, Lesotho, Madagascar, Malawi, Mozambique, Namibia, South Africa, Southern Rhodesia, Swaziland, the United Republic of

Tanzania, and Zambia) is shown in Fig. 26.3. No smallpox had been reported in any of these countries since 1972, except for an outbreak of variola minor in Botswana in 1971–1973, following an importation from South Africa late in 1971 (Table 26.1).

Civil unrest and, indeed, open warfare had been occurring in Angola, Mozambique and Southern Rhodesia since the mid-1970s. South Africa, Namibia (which was controlled by South Africa) and Southern Rhodesia (then regarded by the United Nations as a British colony) were not represented at the

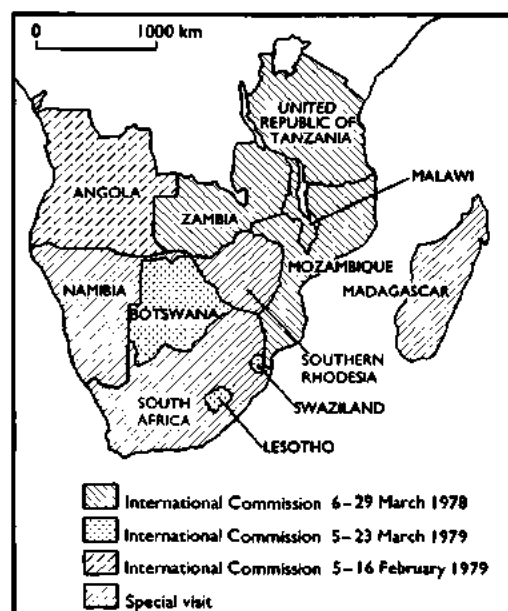

Fig. 26.3. Countries of southern Africa certified free of smallpox by international commissions or visited by a member of the Global Commission or WHO-designated expert before certification by that Commission.

World Health Assembly. This complicated the organization of certification by international commissions. Eventually such commissions were able to visit Angola and Mozambique, where they met with no difficulties. However, there were political difficulties in organizing WHO-sponsored international commissions to certify smallpox eradication in Southern Rhodesia and Namibia, and attempts to arrange for an international commission to visit South Africa (which provided the only route of entry to Namibia) were thought unlikely to be successful or at best unduly time-consuming, owing to political factors. The recommendation of the Consultation on the Worldwide Certification of Smallpox Eradication that an international commission should visit these 3 countries (see Chapter 24) was therefore not followed. Instead, arrangements were made to obtain country reports and other necessary data by organizing visits by a Global Commission member and WHO consultants who were acceptable to the respective national governments. This proved to be quite straightforward in Southern Rhodesia and Namibia, but several visits to South Africa were needed before the requisite data could be obtained.

### Logistics

Experience in western and central Africa had shown clearly the difficulties faced by the small staff of the Smallpox Eradication unit and the relevant personnel in the WHO Regional Office for Africa in arranging simultaneous precertification activities in many countries. Furthermore, it was impossible to find experts of sufficient experience to

Table 26.1. Numbers of reported cases of smallpox in 12 countries of southern Africa, 1967–1974

Country	1967	1968	1969	1970	1971	1972	1973	1974
Malawi	38	61	65	39	10	0	0	0
Mozambique	104	145	11	0	0	0	0	0
United Republic of Tanzania	1 629	455	117	32	0	0	0	0

South Africa	43	81	246	121	10	1	0	0
Southern Rhodesia	30	10	33	6	0	0	0	0
Madagascar	0	0	0	0	0	0	0	0

form the international commissions if members were required to travel too often and to too many different countries. To simplify certification, 2 groupings were therefore made of small numbers of countries, as follows: (1) Malawi, Mozambique, the United Republic of Tanzania, and Zambia; and (2) Botswana, Lesotho and Swaziland. The remaining 5 countries were dealt with separately. Angola, in particular, was a large country in which there had been serious civil disturbances both before and after it achieved independence in 1975 so that it was uncertain whether commission members would be able to travel extensively enough for certification to be possible. For this reason, a separate international commission was established for Angola so as not to prejudice the certification of any other country that might be grouped with it. The political problems associated with Namibia, South Africa and Southern Rhodesia have already been mentioned, while Madagascar, as an island, was a special case.

For the first time since certification in South America in 1973, the problem had to

be faced that the variety of smallpox most recently present in some of these countries was mainly variola minor. In this situation, pockmark surveys, which had proved so useful in the countries of western and central Africa, were much less likely to reveal recent transmission of smallpox, because facial scars persisted in less than 10% of patients. To supplement such pockmark surveys as were performed, intensive surveillance for cases of chickenpox was carried out, and specimens were collected for laboratory examination—a procedure which reached its apogee in certification operations in the Horn of Africa (see Chapter 27). Surveillance for cases of chickenpox provided a measure of the sensitivity of the reporting system and permitted specimens to be collected from cases and outbreaks over a wide area. If cases had mistakenly been diagnosed as chickenpox instead of variola minor, this would be revealed by laboratory studies. Moreover, by obtaining material from outbreaks in which a patient had died, presumably of chickenpox, the likelihood of detecting smallpox, if it were present, was increased.

### Time Schedules for Certification

Since there were so many countries for which certification was required by the end of 1979, all certification activities had to meet a strict time schedule. Further, if one of a group of neighbouring countries failed to achieve certification, none of the countries in that group could be certified. Various measures were taken to accelerate certification and maintain uniform progress—e. g., countries were requested to send information on the progress made in preparations for certification to the WHO Regional Office for Africa by cable every month. An example of such a request is reproduced below. Although formal communications were with the Regional Office, it was important that the epidemiologists in Nairobi and the Smallpox Eradication unit in Geneva should be kept informed of the situation; hence a copy of the cable was sent to each of them.

#### *Outgoing cable:*

"Reference progress SME [smallpox eradication] certification activities from now onwards please deliver to AFRO [Regional Office for Africa] a monthly cable to monitor status commission preparation including AAA cumulative totals pockmark surveys since surveys began BBB total number localities chosen for field surveys CCC total number localities visited by teams DDD total number of persons seen in schools or elsewhere EEE number of persons with facial pockmarks FFF number of specimens collected for laboratory study stop Please begin this cable report thirty October and forward thereafter on day thirty of subsequent months to AFRO with copy SME HQ [Smallpox Eradication unit] and ICP ES 005 [Epidemiological Surveillance of Diseases Inter-country Project] epidemiologists Nairobi and Maputo."

## Malawi, Mozambique, United Republic of Tanzania, and Zambia

### *Precertification activities*

These countries had recorded their last cases of smallpox between 1969 and 1971 (Table 26.1). Dr Ziaul Islam, a WHO epidemiologist based in Nairobi, who had worked on both the western and central African certification programmes, took the major role in precertification activities in this group of countries.

The preparation of country reports started early in 1977 while the certification of central Africa was in progress. In July 1977, a coordination meeting attended by WHO regional and Headquarters staff was held in Brazzaville, Congo, to assess progress. It was decided at this meeting that, in addition to pockmark surveys, a programme for the surveillance of chickenpox cases, with emphasis on the collection of specimens for laboratory examination, should have a high priority in the preparations for certification. It was proposed that at least 100 specimens from chickenpox patients should be collected in each country, from outbreaks separated in both space and time. By October 1977, Dr Islam had visited Malawi, the United Republic of Tanzania, and Zambia at least once to assist with the pockmark surveys and chickenpox surveillance. It was estimated that by December 1977 all the preparations for visits by an international commission would be completed.

*Pockmark surveys.* As part of the preparations for certification, pockmark surveys were

carried out in each country, covering 3.2% of their combined population of 38.2 million (Table 26.2). No pockmarked children were seen among 70 621 children of preschool age, nor had any person with facial pockmarks suffered from smallpox later than 1970.

*Chickenpox surveillance.* In accordance with the decision made at the coordination meeting at Brazzaville in July 1977, all countries had collected a number of specimens from cases clinically diagnosed as chickenpox (Table 26.3). When examined at the WHO collaborating centres, no specimens showed poxvirus particles by electron microscopy and cultures for orthopoxviruses were uniformly negative. Herpesvirus particles were seen in 26% of the specimens.

*Continued transmission in Malawi.* During preparations for certification in Malawi, evidence was obtained which showed that smallpox transmission had continued for a long period of time without being recognized by the health services. The last reported case occurred in December 1969. In April 1972, Dr Islam discovered in a remote part of southern Malawi 48 individuals with facial pockmarks who had contracted their infections between April 1970 and February 1971—i.e., up to 14 months after the last reported case (see Chapter 20). Subsequently, during the precertification surveys, a joint Malawi-WHO team discovered a pockmarked girl and 2 other possible cases in the same area who gave a history of having been infected in September 1972. The exact status of these cases was never determined, but it was eventually concluded that, among the illiterate rural population, information given as to

### Laboratory Diagnosis of Chickenpox

During precertification activities in many countries, large numbers of specimens from cases of chickenpox were submitted for laboratory testing to WHO collaborating centres. The varicella-zoster virus, which causes chickenpox, does not grow on the chorioallantoic membrane and grows only slowly in special kinds of cultured cells. However, typical enveloped herpes virions can be seen with the electron microscope in preparations made with fresh vesicular fluid (see Chapter 2, Plate 2.16).

Most reports from WHO collaborating centres showed a rather low percentage of sightings of herpes virions with the electron microscope in material that came from cases of chickenpox, compared with the very high percentage of positive results for pox virions from cases of smallpox. This is explained by the fact that the enveloped herpes virions are much more fragile than pox virions and often failed to survive intact during the process of shipment from the field to the laboratory.

Table 26.2. Malawi, Mozambique, United Republic of Tanzania, and Zambia: results of facial pockmark surveys conducted during precertification activities, 1977-1978

	Malawi	Mozambique <sup>a</sup>	United Republic of Tanzania	Zambia
Population, 1977 (millions)	5.5	10.6	17.0	5.1
Percentage of population seen	5.5	1.4	1.9	9.0
Number of preschool children examined	19 844	6 303	15 199	29 275
Number with pockmarks	0	0	0	0
Number of school-age children examined	242 068	69 543	206 021	364 194
Number with pockmarks <sup>b</sup>	737	161	1 242	1 261
Number of adults examined	42 050	70 908	97 058	65 763
Number with pockmarks <sup>b</sup>	179	523	657	301

Total number with pockmarks <sup>b</sup>	916	684	1 899	1 562

<sup>a</sup> In addition, in surveys carried out during the national mass vaccination campaign (June 1976-February 1978), 35 589 persons were found with facial pockmarks among 7 379 265 persons examined. None of them had contracted smallpox after 1969.

<sup>b</sup> Due to smallpox contracted before 1971.

Table 26.3. Malawi, Mozambique, United Republic of Tanzania, and Zambia: laboratory examination of specimens from cases clinically diagnosed as chickenpox, 1977-1978

Country	Number of specimens	Number positive for:		Number negative
		Poxvirus	Herpesvirus	
Malawi	319	0	62	257
Mozambique	65	0	20	45
United Republic of Tanzania	58	0	18	40
Zambia	86	0	36	50
Total	528	0	136	392

the year of illness was unreliable, and that the last case in Malawi had occurred in an outbreak that terminated spontaneously in 1971 without being detected by health staff.

*Difficulties in precertification activities.* WHO-assisted national smallpox eradication programmes had operated in Malawi, the United Republic of Tanzania, and Zambia, but the sensitivity of the surveillance system for smallpox had diminished in each of these countries since 1974. WHO had not been involved in smallpox eradication work in Mozambique. The precertification surveys just described were made possible only by detailing a WHO epidemiologist to work with designated national health workers in each country. Some logistic problems arose—e.g., in Mozambique, in which available resources were insufficient to permit the carrying out of a pockmark survey and extra funds had therefore to be provided to cover petrol costs and living allowances. Three new ve-

hicles were also needed, but only for 2-3 months, so that it would have been wasteful to purchase them. Furthermore, they could not have been obtained in time, since procurement usually took 12 months. This problem was solved when the vehicles were made available by the WHO Expanded Programme on Immunization and money to cover local expenses was provided by WHO.

#### *Visit by the International Commission, 6-29 March 1978*

An International Commission for the Certification of Smallpox Eradication met in Maputo, Mozambique, from 6 to 9 March 1978. After reviewing the data from all 4 countries, the Commission set up 4 teams, one for each country, and reassembled for its final meeting in Lusaka, Zambia, 27 to 29 March.

After extensive travel throughout each country and examination of the reporting networks and of the data provided in the country reports, the Commission decided that, if smallpox transmission had continued after the date of the last known case, it would have been detected. The circumstances of the missed outbreak in Malawi were carefully scrutinized, but the epidemiological evidence indicated that the last case had occurred in 1971. The Commission noted that, even if the disease had persisted until September 1972, this was over 5 years ago, and the local situation had been examined in detail both by the joint Malawi-WHO team in precertification activities and by the Commission member during his visit. At its final plenary meeting in Lusaka the Commission agreed

that the 4 countries should be certified to be free of smallpox.

### **Botswana, Lesotho and Swaziland**

#### *Coordination meeting*

During the International Commission's visit to Lusaka in March 1978, mentioned above, a coordination meeting was held to discuss strategies for the certification of the remaining countries in southern Africa. It was attended by Dr Celal Algan and staff from the WHO Regional Office for Africa, Dr Joel Breman, formerly of the Center for Disease Control, Atlanta, USA, who had recently joined the Smallpox Eradication unit, and Arita. Apart from the Horn of Africa, where smallpox remained endemic until 1977, the last case in Africa had been reported in Botswana in November 1973. The small landlocked countries of Lesotho and Swaziland had experienced their last outbreaks in 1962 and 1966 respectively.

Although the 6 adjacent countries of Botswana, Lesotho, Namibia, South Africa, Southern Rhodesia and Swaziland formed an epidemiological unit (see Fig. 26.3), the coordination meeting decided that it would be very time-consuming and perhaps politically difficult to arrange for simultaneous precertification surveys and the certification of these countries by one or even several international commissions. Botswana was the only one of them in which WHO had been involved in a smallpox eradication programme when, after the outbreak there in 1971, a WHO team had assisted an augmented national programme. It was decided that arrangements should be made for the visit of an international commission to Botswana, Lesotho and Swaziland in March 1979, and that preparations for precertification activities in those 3 countries should begin immediately. Other measures were to be taken to obtain the information necessary to certify smallpox eradication in Namibia, South Africa and Southern Rhodesia (see below).

Table 26.4. Botswana, Lesotho and Swaziland: results of facial pockmark surveys conducted during precertification activities, 1978-1979

<sup>a</sup> Due to smallpox contracted before 1974.<sup>b</sup> Due to smallpox contracted before 1971.*Precertification activities*

The last outbreak of smallpox in the region had been due to very mild variola minor in Botswana in 1971-1973 (see Chapter 20), and variola minor was the predominant variety of smallpox recently prevalent in South Africa, by which Lesotho was completely and Swaziland almost completely surrounded. However, outbreaks of variola major had occurred in all these countries in the past, and it was decided to carry out both pockmark surveys and chickenpox surveillance. Dr Moïses Altman, a WHO epidemiologist stationed in Maputo, Mozambique, assisted the national health authorities in their preparations for the commission's visit. Progress was initially rather slow, but by January 1979 all 3 countries had prepared country reports and completed pockmark and chickenpox surveys.

**Pockmark surveys.** The pockmark surveys covered a large proportion of the small populations of the 3 countries (Table 26.4). No facial pockmarks were seen in 44 985 children of preschool age and only 6 cases (all in Botswana) were found among 291 612 schoolchildren. Pockmarks were somewhat more common in adults, being seen in 0.26% in Botswana and a smaller proportion in Lesotho and Swaziland, and heavy facial scarring was found only in adults, reflecting the outbreaks of variola major in the 1950s and 1960s.

**Chickenpox surveillance.** Specimens were collected from cases of chickenpox during precertification surveillance, care being taken to obtain specimens from as many separate outbreaks as possible. They were examined at WHO collaborating centres. None contained poxvirus, but herpesvirus particles were seen

Table 26.5. Botswana, Lesotho and Swaziland: laboratory examination of specimens from cases clinically diagnosed as chickenpox, 1978-1979

Country	Number of specimens	Number positive for:		Number negative
		Poxvirus	Herpesvirus

Total	359	0	101	258

with the electron microscope in 28% of the specimens (Table 26.5).

*Visit by the International Commission, 5-23 March 1979*

The first meeting of the International Commission was held in Gaborone, Botswana, from 5 to 7 March 1979. In addition to examining the country reports for these 3 countries, the Commission reviewed the data available at that time on smallpox eradication in the 3 neighbouring countries, Namibia, South Africa and Southern Rhodesia, because these 6 countries formed an epidemiological unit. The Commission then divided into 3 groups, which visited Botswana, Lesotho and Swaziland respectively, and reassembled for final discussions in Mbabane, Swaziland, between 21 and 23 March.

During their visits, Commission members themselves carried out pockmark and vaccination scar surveys, though necessarily on a much smaller scale than in the national

**Plate 26.2.** Participants in the briefing meeting of the International Commission for the Certification of Smallpox Eradication in Botswana, Lesotho, and Swaziland, held in Gaborone, Botswana, 7 March 1979. *Left to right, front row: I.H. Chu (WHO), M. Altmann (WHO), **G. Meiklejohn (USA)**, **W. Koinange (Kenya)**, **I. Tagaya (Japan)**, **D. Chitemba (Malawi)**, **P.E.M. Fine (USA)**; back row: R.A. Ilbor (WHO), J.P. Breman (WHO).* The names of the Commission members are in bold type.

surveys (Table 26.6). They discovered a higher proportion of pockmarked schoolchildren and adults than had been found in the national surveys in Botswana and Swaziland, but fewer in Lesotho. In any case, even these higher frequencies were quite low (0.26% and 0.29% in schoolchildren in Botswana and Swaziland respectively) and no pockmarked children under the age of 6 were found, out of a total of 2533 examined.

There was some doubt among Commission members in Botswana whether smallpox

transmission there had been interrupted in 1973 or had extended into 1974. Two suspected cases of smallpox in children had occurred in 1974, but it was impossible to confirm or disprove the diagnosis.

The vaccination scar survey conducted by Commission members revealed a high vaccination coverage of the population in all 3 countries; in the age group under 15 years, for example, it was 96% in Botswana, 85% in Swaziland and 72% in Lesotho. In Botswana, refugees, bushmen and a religious sect whose

<sup>a</sup> Due to smallpox contracted before 1974.

<sup>b</sup> Due to smallpox contracted before 1971.

members objected to vaccination on principle were considered as high-risk groups among whom the transmission of smallpox was more likely to continue. However, national vaccination surveys and visits by Commission members showed satisfactory vaccination coverage in each of these groups.

Because the variety of smallpox most recently prevalent in these 3 countries had been variola minor, the absence of pockmarks in children was less significant than in the majority of other countries, but the absence of variola virus in specimens taken from cases diagnosed as chickenpox and the high level of vaccinia immunity were persuasive. Noting that there had been no evidence of confirmed smallpox since 1973 or of suspected cases since 1974, the Commission certified that smallpox had been eradicated from Botswana, Lesotho and Swaziland.

### South Africa

With a population of 22.8 million in 1970, South Africa was the most populous country in southern Africa. Variola major and variola minor had been endemic up to the Second World War, but thereafter only variola minor had persisted as an endemic disease, and was not regarded very seriously by the health authorities. Apart from a visit to South Africa in 1972 by Henderson (see Chapter 20), the country had had no contact with the WHO smallpox eradication campaign and had not established a national smallpox eradication programme. Smallpox was regarded as one of the diseases for which vaccination should be provided, but was considered to be of minor importance compared with poliomyelitis, measles, diphtheria, and other diseases.

#### *Arrangements for certification*

Following the Consultation on the World-wide Certification of Smallpox Eradication in October 1977, the Director-General of WHO wrote to the South African Minister of Health and Welfare to propose that the South African government should participate in the global certification of smallpox eradication. In his letter he suggested that a visit early in 1978 by Fenner, who had been the chairman of the Consultation, would be a useful way to begin this activity. Within 10 days of the dispatch of this letter, South Africa informed WHO by cable of its willingness to participate

in these certification activities and to provide every assistance during Fenner's visit.

*Visit by Fenner, 19 January-19 February 1978.* The purpose of the visit was three-fold: (1) to advise South African health officials on how to prepare a country report for submission to the Global Commission; (2) to emphasize the importance of chickenpox surveillance and make arrangements for the collection of specimens for laboratory examination by WHO collaborating centres; and (3) to obtain an impression of the recent history of smallpox and rural health services in South Africa (including some of the "black homelands"). Fenner's itinerary is shown in Fig. 26.4. With the help of the South African government, the trip was extended to include Namibia (see below). He was cordially received by government and provincial health officials (see box) and visited infectious disease hospitals, university medical schools, diagnostic laboratories in Johannesburg and Cape Town, and rural health centres in northern Transvaal and 3 of the "black homelands", Bophuthatswana, Lebowa and Transkei.

The laboratory services were found to be of high quality and a network of diagnostic laboratories covered most of the country. However, their practice of testing for ortho-

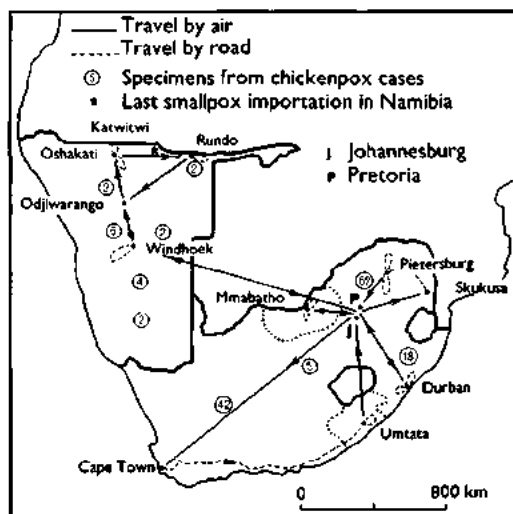

Fig. 26.4. Itinerary of the visit to South Africa and Namibia by the chairman of the Global Commission, Dr F. Fenner, 19 January-19 February 1978, and numbers of specimens from cases of chickenpox from each of the provinces of South Africa and various parts of Namibia.

### Collaboration between South Africa and WHO on Smallpox Eradication

The following note prepared by Fenner on his return from South Africa illustrates that country's willingness to cooperate with WHO's global certification activities:

"Everywhere I went I was received with great cordiality, and there were frequent expressions of satisfaction that WHO had arranged the visit. No effort was spared to enable me to see what I regarded as the 'vulnerable' areas, the more heavily populated parts of Namibia near the Angolan border and the northern parts of Transvaal (Lebowa) and Bophuthatswana, near Botswana.

"I was driven around the countryside and to clinics and hospitals by senior health officials, health inspectors or nursing sisters over a distance of more than 3000 km, and a chartered plane was made available for 3 days. Such travel afforded opportunities for extensive informal discussion of the health conditions and the complex politics of these parts of Africa, as well as observation of the countryside and living conditions in the rural areas, and the rural hospitals and clinics."

poxviruses by growth in tissue culture rather than on the chorioallantoic membrane, and reporting positive results as indicating a "member of the vaccinia-variola group" was confusing (see Chapter 20). Variola virus stocks were held in the National Institute for Virology, but the South African Director-General of Health would not agree to a request by Fenner that they should either be transferred to a WHO collaborating centre or destroyed. In fact, it was not until December 1983 that they were finally destroyed (see Chapter 28).

Vaccine was produced in a laboratory in Cape Town for use locally and in some neighbouring countries—e.g., Southern Rhodesia. Tests on freeze-dried vaccine carried out in 1970 by the WHO Collaborating Centre for Smallpox Vaccine in Bilthoven, Netherlands, showed that it met WHO standards.

*Preparation of the country report.* It was suggested that South Africa should submit its country report by 1 June 1978 and complete the chickenpox survey in October 1978, so that the situation could be reviewed at the Global Commission meeting in December 1978. However, when no material had arrived by 12 September, Arita sent a cable to Pretoria requesting the submission of a country report documenting smallpox eradication as soon as possible. To avoid further delay, Fenner revisited South Africa briefly in mid-October, and Dr Nicole Grasset, formerly the regional smallpox adviser in the WHO South-East Asia Region, who had lived in South Africa in her youth, visited the country in November and brought data and a draft report back

to Geneva, where it was finalized by staff of the Smallpox Eradication unit.

The delay in sending the results of the chickenpox surveys was due to the seasonal character of the disease; outbreaks occur in spring and, in the Southern Hemisphere, this starts in September, so that, by October, there had been too few to enable the stipulated 100 specimens to be collected.

#### *Review of country report by the Global Commission, December 1978*

The country report and the results of an incomplete chickenpox survey were presented to the Global Commission at its meeting in Geneva from 4 to 7 December 1978. The Commission noted that South Africa had relatively well developed health services, as shown by the overall doctor to population ratio of 1:1806 and registered nurse to population ratio of 1:573. In addition, 5660 health stations were responsible for reporting communicable diseases. After the last known outbreak in 1971, when special efforts were made to achieve high vaccination rates in the northern Transvaal (see Chapter 20), smallpox vaccination was being performed as part of a well-organized immunization programme which also provided polio-myelitis, BCG and diphtheria-pertussis-tetanus vaccination.

The results of facial pockmark and vaccination scar surveys carried out in widely separated rural and urban areas during 1978 are shown in Table 26.7. An additional survey of 17 064 children under 15 in Bophuthatswana and Transkei revealed none with facial pock-

Transvaal	62	0	25	37
Total	127	0	42	85

marks and 67.6% with vaccination scars. Four adults with facial pockmarks gave histories of attacks of variola major many years earlier.

When the Global Commission met in December 1978, no data were available on the laboratory examination of specimens from cases of chickenpox, and it was therefore decided to delay certification pending the arrival of the results of this survey. By June 1979, 127 specimens had been submitted for examination, the majority coming from the northern Transvaal (see Fig. 26.4), where the last outbreak of smallpox had occurred in 1971. All were negative for poxvirus, but herpesvirus particles were seen in 33% of the specimens (Table 26.8).

After receipt of the results of the examination of the first 100 specimens, Arita wrote to members of the Global Commission, who, on the basis of their review of the situation in December 1978 and the results of the chickenpox survey, agreed on 17 April 1979 that smallpox eradication had been achieved in South Africa.

### Namibia

Although the United Nations had terminated the South African mandate over Namibia

in 1966 and the South African presence there had been declared illegal by the International Court of Justice in 1971, the country was in fact controlled and administered by South Africa, under the name "South West Africa". In this sparsely populated country, the highest population density being 7.5 persons per square kilometre in Ovamboland, adjacent to the border with Angola, endemic smallpox was said never to have been present, though there had been occasional importations from Angola, most recently in 1956. Endemic smallpox had been eliminated from Angola in 1959 (see below) and although cases had occurred as recently as 1973 in Botswana, these were in the eastern part of that country, separated from Namibia by the Kalahari desert. The South African Institute for Medical Research operated a branch laboratory in Windhoek, the capital, and small laboratories in some other towns in Namibia.

### Visit by Fenner, 5-9 February 1978

During his trip to South Africa early in 1978, Fenner also spent 5 days in Namibia (see Fig. 26.4). He met health officers and staff in hospitals and laboratories, obtained information on health services, especially the surveillance and control of communicable diseases, visited schools and conducted a limited vaccination scar survey. After his departure, a country report was prepared by the South African health authorities and sent to the Global Commission.

### Review of the country report by the Global Commission, December 1978

The country report was considered at the meeting of the Global Commission in December 1978. It followed the usual lines, describing the geography and demography,

health administration, history of smallpox and records of vaccination activities. Between 1969 and 1978, 10 specimens had been examined for suspected smallpox at the National Institute for Virology in Sandringham; all were negative. Pockmark and vaccination scar surveys had been conducted throughout the country in April–November 1978 (Table 26.9). The 3 pockmarked adults found were Angolans who said that they had suffered from smallpox in childhood.

During 1978 and 1979, 18 specimens collected from cases clinically diagnosed as chickenpox (see Fig. 26.4) were examined in a WHO collaborating centre; none contained poxvirus but 9 showed herpesvirus particles.

On the basis of the history of smallpox in Namibia, the low probability of importations from adjacent countries during the previous decade, the results of the facial pockmark surveys and the high vaccination rate in individuals over 5 years of age, the Global Commission certified that smallpox had been eliminated from Namibia.

### Southern Rhodesia (Zimbabwe)

Southern Rhodesia was a British colony until 1980, when it attained independence and was renamed Zimbabwe. In 1965 the white colonists had made a unilateral declaration of independence and since then the country had been in a state of civil war. Legally, in 1978, it remained under the jurisdiction of the United Nations Sanctions Committee. In order to obtain information on the smallpox situation, the Director-General of WHO wrote to the Southern Rhodesian authorities requesting that 2 WHO consultants should be allowed to visit the country to assess whether smallpox had been eliminated. A favourable reply having been received, Dr Nicole Grasset and Dr Gordon Meiklejohn,

both highly experienced in smallpox eradication activities, visited the country in January 1978.

### *Visit by Dr Grasset and Dr Meiklejohn, 10–30 January 1978*

Since Southern Rhodesia was a much smaller country, the objectives of this visit differed from those of Fenner's visit, mentioned above, to South Africa and Namibia. The consultants' aim was to obtain enough information, by travel and inquiry, and supported by subsequent investigations by local personnel, to be able to submit to the Global Commission a definitive report on the smallpox situation in Southern Rhodesia.

The consultants were warmly received by the local authorities (see box) and after initial consultations in Salisbury (Harare), they travelled separately around the 5 provinces, carrying out extensive pockmark and vaccination scar surveys as well as evaluating the level of surveillance of infectious diseases by health personnel. Subsequently, national health personnel carried out further and more extensive studies. The consolidated results of all these surveys are shown in Table 26.10.

In their inquiries, the consultants observed that there was a remarkable lack of knowledge about smallpox among persons under 25 years of age. Almost without exception they failed to recognize the smallpox pictures on the recognition cards and stated that they had never seen or known of the presence of the disease. On the other hand, many older persons knew about smallpox from their childhood, and 0.26% of adults surveyed had facial pockmarks, the most recent being said to date from an illness in 1966.

In addition to their field survey, the consultants commented on the health services, which they described as extensive, well

<sup>a</sup> Due to smallpox contracted before 1967.

### Attitude of the Southern Rhodesian Authorities to the Visit by WHO Consultants

Dr Grasset reported as follows: "Dr G. Meiklejohn and myself were everywhere received with great cordiality and everything was done to facilitate our work in Rhodesia . . . Maps, charts and tables concerning the smallpox programme in Rhodesia since 1954 were given to us, and the smallpox activities and other health programmes were freely discussed.

"... In order to carry out surveys in as many localities as possible, half the country's territory was covered by Dr Meiklejohn and the other half by myself . . . The Chief Health Inspector accompanied Dr Meiklejohn throughout his travels, and I was escorted by different European and African provincial health officials.

"As the majority of localities we had to visit for epidemiological reasons were in areas bordering Mozambique, Zambia and Botswana, where few or no civilians travel due to civil warfare, special arrangements were made to bring us as near as possible to the villages by chartered or government four-seater planes. From the rough air strips, we were usually provided with a metal-protected lorry accompanied by armed African soldiers. In particularly dangerous areas, two military jeeps with soldiers escorted us throughout the day and soldiers were placed on the airstrips to assure our security at the departure of the charter plane.

"As every day we had to examine a few thousand children in one to four localities, advance planning was made by the authorities, i.e., the population was grouped at gathering points, and up to 8 African health assistants were made available to assist us in our work.

"On no occasion was any information requested kept from us."

planned and supported by excellent communications. There was a medical school in Salisbury; the health personnel included many European nurses and physicians, a large proportion of whom had undergone training in public health and tropical medicine; and an extensive network of 83 mission hospitals existed. Because of the civil war, health staff were working under extremely difficult circumstances, often at the risk of personal injury or death. Although smallpox was at the top of the list of notifiable diseases, the country had never set up a separate smallpox eradication programme. Mobile vaccination teams sought to vaccinate the entire population against smallpox in a 3-year cycle, using liquid smallpox vaccine purchased from South Africa. There were no systematic search operations and, apart from reporting during an outbreak, no routine "nil" reports. Reliance was placed on the extensive and well-distributed network of health units and on the alertness of staff in high-risk areas. This approach appeared to have been reasonably successful in detecting almost all outbreaks, and transmission was interrupted in 1970. The instability in some border areas raised doubts as to the ability of this health structure to detect outbreaks rapidly in those areas if

there should be an importation, but the neighbouring countries—Botswana, Mozambique, South Africa and Zambia—had been free of smallpox since 1973 or earlier.

The consultants found no evidence of smallpox transmission within Southern Rhodesia or of importations since the last reported outbreak there in 1970. It was their opinion that, because the health units were numerous, geographically well distributed and staffed with well-trained and alert personnel, any case of smallpox that might have occurred after 1970 would have been detected. Facilities for laboratory diagnosis, including electron microscopy, were available in Salisbury and many specimens had been tested between 1970 and 1977, all with negative results. After the consultants' visit, a further 23 specimens obtained from patients with what was diagnosed clinically as chickenpox were examined in a WHO collaborating centre. Herpesvirus particles were found in 10 of them but poxvirus in none.

### *Review by the Global Commission, December 1978*

At its meeting in December 1978 the Global Commission reviewed the consultants' report and the results of the pockmark and

vaccination scar survey supplied by the government, and certified that Southern Rhodesia was free of smallpox.

### Angola

The only countries remaining for assessment in southern Africa were Angola and the island of Madagascar. At the coordination meeting held in Lusaka in March 1978, it had been decided that the certification of Angola should be carried out by an international commission in February 1979.

The last reported cases of smallpox in Angola had occurred in 1966. Although the country had suffered from political instability since 1961, there had been a good vaccination programme, in which freeze-dried vaccine had been used, until 1975. Variola minor was endemic up to 1959, and outbreaks of variola major had occurred following importations from Zaire during the 1960s, the last taking place in 1966. Each of these was investigated by state epidemiologists and confirmed by virus isolation at a laboratory in Luanda. The extensive national vaccination campaign extended through 1974 but was then sharply curtailed because of the civil war, which culminated in national independence in 1975. By then, more than 3 years had elapsed since the last outbreak in Zaire, which had been the source of earlier importations. However, in 1978 many areas were regarded as inaccessible and it was thought that it would be difficult to carry out pockmark surveys and obtain specimens from cases of chickenpox in those parts of the country.

#### *Precertification activities*

Dr Joel Breman of the Smallpox Eradication unit helped to plan the precertification programme and Dr René F. M. Collas, a WHO epidemiologist, and Mr José F. Verani, a WHO technical officer, who were stationed in Angola in connection with other WHO projects, assisted the national health officials. In August 1978 Dr Clovis H. Tigre, a Brazilian epidemiologist, visited Angola to review the progress of field surveys and the preparation of the country report. He found that little had been done.

In November 1978, at Arita's request, Dr Francisco J. C. Cambournac, a former resident of Angola who had been Director of the WHO Regional Office for Africa but had

retired to Portugal, provided valuable data on smallpox in Angola before 1975, the year of independence. The country report was finally prepared later that month, by which time 79 specimens had been collected from chickenpox patients. However, the field survey had been delayed because of poor communications and lack of resources, and it was doubtful whether all the data would be available for the visit of the International Commission scheduled for February 1979. Early in December, after a meeting at the Ministry of Health between government officials and the WHO programme coordinator in the country, the survey proceeded more rapidly and by early January 1979 all preparations had been completed.

*Pockmark survey.* The pockmark survey carried out by the national health authorities covered all the provinces (Fig. 26.5) and 11% of the total population. About 0.8% of the adult population and 0.04% of school-age children had facial pockmarks, but only 1 pockmarked child was found in the preschool age group (Table 26.11), and it was decided that the scarring had been caused by chickenpox.

*Chickenpox surveillance.* Variola minor had virtually replaced variola major in Angola in

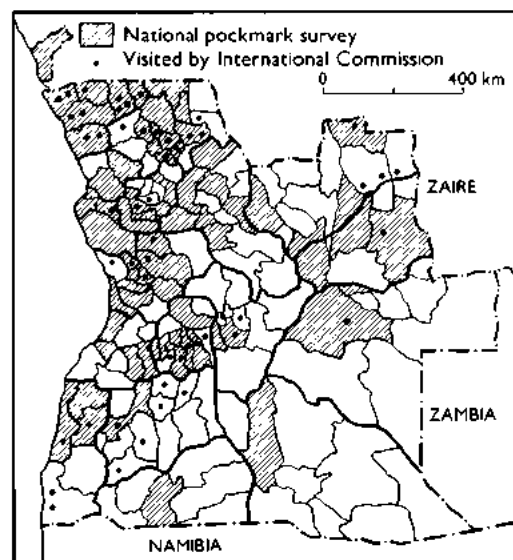

Fig. 26.5. Certification activities in Angola: municipalities covered by the national pockmark survey, July–December 1978, and those visited by members of the International Commission for the Certification of Smallpox Eradication in Angola, 5–16 February 1979.

Table 26.11. Angola: results of facial pockmark survey in July-December 1978, by age group

Age group	Total number	Persons examined	
		Number	%
Preschool children	81 572	1 <sup>a</sup>	0
School-age children	444 401	177 <sup>b</sup>	0.04
Adults	218 454	1 807 <sup>b</sup>	0.83

<sup>a</sup> One child had facial scarring which resembled pockmarks caused by smallpox, but after further examination it was decided that the scarring had been caused by chickenpox.

<sup>b</sup> Due to smallpox contracted before 1974.

the 1950s and had been present together with variola major in neighbouring countries (Zaire and Zambia) until the late 1960s. A total of 122 specimens collected from outbreaks of chickenpox occurring in various provinces (Fig. 26.6) were examined in a WHO collaborating centre; none contained poxvirus but 12 were found to contain herpesvirus particles. This unusually small proportion of herpesvirus-positive specimens was due to a breakdown of the electron microscope during the period concerned, so that much of the material had only been cultured.

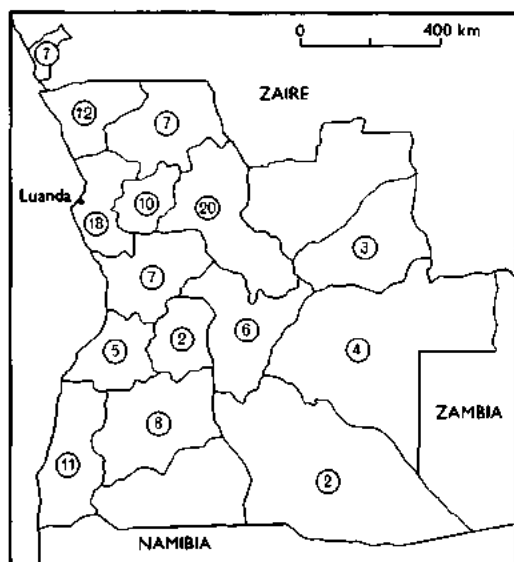

Fig. 26.6. Numbers of specimens collected from chickenpox cases in various provinces of Angola between July 1978 and February 1979.

### *Visit of the International Commission, 5-16 February 1979*

After reviewing the data supplied by the Angolan authorities in Luanda, the Commission formed 5 teams, which travelled widely throughout the country (see Fig. 26.5) before meeting again in Luanda on 15 and 16 February to review the situation. Contrary to the opinion prevailing earlier, members were able to visit most parts of Angola, except the south-east, which bordered on Namibia, a country that had been free of smallpox for decades. During their visits they conducted a facial pockmark survey that covered 28 167 persons, of whom 495 had pockmarks; these were all persons of school age or older and all had contracted the illness causing the pockmarks prior to 1966.

Between 1966 and 1974 there had been a good vaccination programme, 1.5-2.8 million people out of a population (in 1974) of about 6.3 million having been vaccinated annually with freeze-dried vaccine of good quality purchased from a number of European countries. There were 144 reporting units in the 16 provinces and, on average, one-third of them were sending in monthly epidemiological reports. Taking into consideration the absence of smallpox from Angola since 1966 and from neighbouring countries since the late 1960s, the field investigations carried out by the Angolan authorities, and the results of the chickenpox survey, the International Commission certified Angola to be free of smallpox.

### **Madagascar**

Because Madagascar was an island with a relatively small population, it had been possible to interrupt smallpox transmission there during the First World War, and to control effectively the few importations that occurred between 1925 and 1931 (see Chapter 8). The Consultation on the Worldwide Certification of Smallpox Eradication, meeting in October 1977, decided that all that was needed from Madagascar was a country report, which was presented by the government to WHO in December 1977.

An unusual feature of this report was the large number of recorded deaths from chickenpox (Table 26.12). The data for 1972-1975 were supplied in the country report, the other figures by correspondence. These data could

Table 26.12. Madagascar: number of reported cases of and deaths from chickenpox, 1972-1978

Year	Number of cases	Number of deaths	
		Original figures <sup>a</sup>	Revised figures <sup>b</sup>

<sup>a</sup> From the Ministry of Health of Madagascar.

<sup>b</sup> After investigations by Dr Z. Islam in March 1979.

have been interpreted as the result of an unrecognized importation of variola major into Madagascar in 1974 and its subsequent spread and misdiagnosis as chickenpox during 1975 and 1976. The likelihood that this was so was increased when the data by province for 1976 showed that the case-fatality rate for "chickenpox" in the province of Antananarivo was almost 1% (8572 cases; 83 deaths). Correspondence between the Smallpox Eradication unit and health officials in Madagascar failed to elicit a satisfactory explanation for the reported high death rates from chickenpox, and in December 1978 the Global Commission deferred certification pending the provision of further information.

It was arranged that Dr Ziaul Islam should visit Madagascar and investigate the situation. Working there from 26 February to 9 March 1979, he checked the original records for 1972-1978 and discovered that measles deaths had sometimes been attributed to chickenpox, typing errors had been made, and confusion had resulted from using reporting forms for mortality when those intended for reporting morbidity had run out; sometimes no explanation for the figure reported could be found. His final assessment of the numbers of deaths from chickenpox, also shown in Table 26.12, is consistent with the occurrence of chickenpox only.

Dr Islam's report, which also provided some additional information on the health structure and vaccination programme in Madagascar, was distributed to members of the Global Commission on 10 May 1979. They accepted the explanation that the high mortality attributed to chickenpox was due to reporting and/or recording errors and eradication in Madagascar was certified by correspondence on 29 June 1979. Had the Global Commission not made such a decision, arrangements between the Smallpox Eradication unit and the government of Madagascar were in hand to carry out an intensive pockmark survey in the areas in which large numbers of chickenpox deaths had been originally reported, but this did not prove necessary.

## UGANDA AND THE SUDAN

In parallel with the certification activities in the countries of southern Africa, arrangements were made for international commissions to visit the 2 African countries (other than those of the Horn of Africa) for which certification was still required—namely, Uganda and the Sudan. Uganda had reported its last endemic case of smallpox in

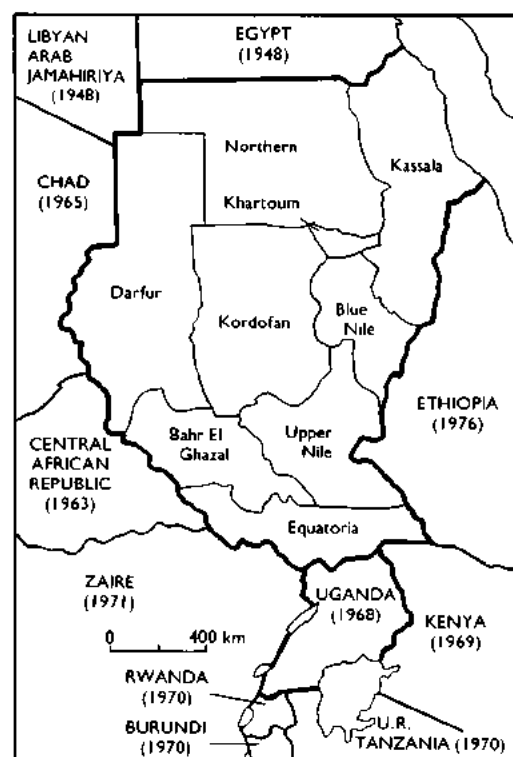

Fig. 26.7. Sudan and Uganda, showing the provinces of the Sudan at the time of the precertification activities and the years in which smallpox ceased to be endemic in neighbouring countries. Uganda was visited by an international commission from 11 to 27 October 1978 and the Sudan by another international commission from 15 to 29 November 1978.

1968, but imported cases had occurred each year between 1969 and 1972, originating from the neighbouring Equatoria Province of the southern Sudan (Fig. 26.7), in which there had been civil disturbances until 1972. The certification of eradication in Uganda was therefore dependent on that in the Sudan. However, certification could not be undertaken in the Sudan until 1978 because of the risk of importations from Ethiopia, in which smallpox remained endemic until August 1976. Plans were therefore made for the certification of the Sudan and Uganda in October-November 1978, by separate international commissions.

## Uganda

### Pre-certification activities

Preparations for certification in Uganda followed the pattern that had been developed in western Africa, where a similar long

interval had occurred between the last reported case and certification (see Chapter 25). Dr Chu In Ho, a WHO epidemiologist stationed in Kampala, assisted the Ugandan health authorities in the preparation of the country report and in conducting pockmark surveys and chickenpox surveillance. For the pockmark survey (Table 26.13), 622 localities widely dispersed over Uganda's 10 provinces were selected and over 1.5 million persons, representing 12.2% of the total population of Uganda, were examined. Most of the more recent outbreaks of smallpox in Uganda had been due to variola minor (see Chapters 8 and 19), so it was not surprising that facial pockmarks were rare, being found in only 0.005% of persons of school age or older. None was ascribed to smallpox infection contracted after 1970.

A WHO-supported virus laboratory in Entebbe had confirmed diagnoses of smallpox in 1970 and 1972, but thereafter had gradually ceased to function. In preparation for

<sup>a</sup> Due to smallpox contracted before 1971.

certification, 118 specimens were collected from cases of chickenpox occurring in all provinces during the period April–September 1978. On examination at WHO collaborating centres, none was found to contain poxvirus particles.

#### *Visit of the International Commission, 11–27 October 1978*

After an initial 3-day meeting in Kampala, the Commission was divided into 3 teams, which between them visited all the provinces. As well as inspecting health units and the reporting system, they carried out facial pockmark surveys (see Table 26.13) which confirmed the results of the larger national survey.

Before certifying that smallpox transmission had been interrupted in Uganda, members of the Commission made a special visit to the Virus Research Institute in Entebbe and confirmed that all stocks of variola virus previously held there had been destroyed on 27 July 1976, after receipt of the letter dispatched from the Smallpox Eradication unit earlier that month (see Chapter 30).

### **Sudan**

A WHO-assisted smallpox eradication programme had been carried out in the Sudan, geographically the largest country in Africa, from 1969 onwards but was not very effective

until 1972 (see Chapter 18). The last endemic case of smallpox had occurred in Bahr El Ghazal Province in December 1972. The requisite 2-year surveillance period after the last known case had been completed by the end of 1974, but the eradication of smallpox was not certified in the Sudan by an international commission until November 1978.

Certification was delayed because the Sudan was at the crossroads of movements by seasonal agricultural workers and pilgrims, some of whom came from western Africa on their way to Mecca, and some from Ethiopia, in which smallpox had been endemic until 1976 (see Chapter 18, Fig. 18.6). The movement of refugees from Ethiopia into the southern Sudan also caused problems. The certification of smallpox eradication in the Sudan could be undertaken with confidence only after transmission had been interrupted in Ethiopia.

The delay in certification caused considerable problems for the Sudanese health authorities, since they had to maintain surveillance for a further 5 years after the last case. However, the fact that they had done so meant that smallpox eradication in the central and eastern parts of the African continent could be certified with much greater confidence. In addition to Ethiopia, the Sudan had borders with the Central African Republic, Chad, Kenya, Uganda and Zaire, from which cases had regularly been imported in the 1950s and 1960s. The absence of importations from these countries into the Sudan between 1972 and 1978 provided additional assurance that transmission had ceased in these countries as well.

#### *Prer certification activities*

After the last case occurred in December 1972, surveillance continued in the Sudan, more than 600 staff being employed for the purpose, including 48 supervisors, 18 assessors and 369 vaccinators, who were distributed throughout the 13 provinces. During this period 1 or 2 WHO epidemiologists or consultants assisted in developing and implementing surveillance. The smallpox eradication staff who contributed in this way included Dr Abdel Hamid el Sayed, as the national director of the programme, and the WHO epidemiologists Mr David Bassett, Dr Donald P. Francis and Dr Satnam Singh.

While the reporting system was being strengthened, programme staff conducted a

systematic search for hidden foci of smallpox, particularly in the southern provinces and the areas bordering on Ethiopia. Active searches were conducted in villages, health establishments, schools, police stations and markets to seek information on cases of diseases with a rash, and a reward was offered. The vaccination programme was also maintained.

*Pockmark survey.* Between 1975 and 1977 smallpox eradication programme staff examined a total of nearly 2 million persons, out of a total population of 14 million, for facial pockmarks (Table 26.14). The few people found with them (0.04% of those examined, all of school age or older) had contracted smallpox before 1972.

*Chickenpox surveillance.* Because of possible diagnostic confusion between variola minor and chickenpox, the latter was made a notifiable disease and, wherever possible, outbreaks were investigated by smallpox eradication programme staff. Between 1973 and 1977, 17 690 cases, including 10 deaths, were reported (Table 26.15). Each year, specimens for laboratory investigation were taken from a number of cases, usually those with unusual features. Of 74 specimens examined in WHO collaborating centres none contained poxvirus.

*Special searches in the southern provinces.* Because of the difficulties of access before 1972, special searches were conducted in Upper Nile and Equatoria Provinces. During two

Table 26.15. Sudan: number of reported cases of and deaths from chickenpox between 1973 and 1977 and number of specimens tested

Year	Number of cases	Number of deaths	Number of specimens tested <sup>a</sup>
1973	5 123	0	11
1974	8 895	0	20
1975	1 832	8	11
1976	1 082	2	16

Plate 26.4. The collection and testing of material from skin lesions in cases of fever with rash, especially in countries where variola minor had recently been endemic, provided assurance that the surveillance system would have detected smallpox if it had occurred.

covered evidence of possible smallpox transmission as late as November 1973. The last confirmed case in the province had occurred in November 1972, in the most densely populated part of Kapoeta District, some 80–100 kilometres from the Lafit mountains, where evidence of possible continued transmission was discovered. Intensive investigations suggested that there had been a number of cases, the last in a 15-month-old boy with facial pockmarks. However, it was impossible to determine precisely the date of onset of the disease. The surveillance team revisited the Lafit mountains 3 times in 1974, and repeatedly thereafter, but failed to find any further evidence of smallpox. During a visit to the area in 1976 evidence was obtained suggesting that the supposed last case in the focus had been infected late in 1972, not late in 1973.

*Special surveillance in areas on the Ethiopian border.* In September 1973, an interregional WHO smallpox eradication programme seminar was held in Addis Ababa. Border surveillance was discussed, and the Ethiopian

and Sudanese governments made arrangements after the seminar for surveillance teams from each country to investigate rumours of smallpox on the other side of the border (see Chapter 21). For example, at the request of Ethiopia in November 1973 and February 1974, a Sudanese team investigated smallpox rumours and vaccinated the inhabitants in the Gabba and Metabel areas of Gojam Province in Ethiopia, which were not easily accessible from the Ethiopian side of the border.

*Visit by a WHO consultant.* In August–September 1977, Dr Gordon Meiklejohn, a WHO consultant, visited Khartoum and assisted in documenting the work of the smallpox eradication programme and subsequent surveillance activities. In May 1978, a further stimulus was given to the discovery of cases of smallpox by the announcement by the World Health Assembly that a reward of US\$1000 would be offered to any person who reported a smallpox case which was confirmed by laboratory investigations in a WHO collaborating centre.

**Plate 26.5.** Some of the participants at the meeting of the International Commission for the Certification of Smallpox Eradication in the Sudan, 29 November 1978. *Left to right: R.A. Khan (WHO), C. Lerche (Norway), W. Koinange (Kenya), Yemane Tekeste (Ethiopia), A.H. El Sayed (Sudan), J.G. Breman (WHO).* The names of the Commission members are in bold type.

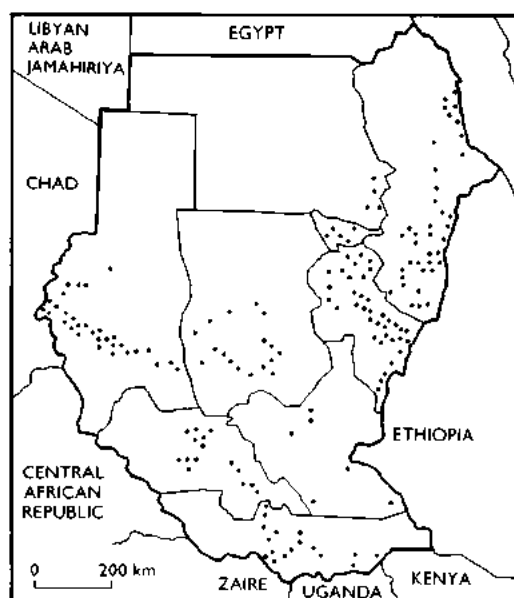

Fig. 26.8. Localities in the Sudan visited by members of the International Commission for the Certification of Smallpox Eradication, 15-29 November 1978.

#### *Visit of the International Commission, 15-29 November 1978*

After a brief meeting in Khartoum, field visits were made by 9 separate teams over a period of 12 days. Because of the large size of the Sudan, an aeroplane was made available by the United Nations Development Programme to help to cover critical areas in the northern and eastern provinces (Fig. 26.8). During their visits, Commission members carried out facial pockmark (see Table 26.14) and vaccination scar surveys.

The International Commission found nothing to cause them to doubt the claim that smallpox transmission had been interrupted in the Sudan at least 5 years earlier, and certified the country to be free of smallpox.

### SOUTH-WESTERN ASIA

Several countries in south-western Asia required certification by international commissions or other special measures (Fig. 26.9). They fell into 3 groups.

Yemen and Democratic Yemen were geographically close to the last remaining endemic countries in the world, Ethiopia and Somalia, and certification activities were delayed there until nearer the time when the

Horn of Africa would itself be visited by international commissions. Because of political differences between the two countries, they were visited by separate international commissions in June 1979.

To the north-east lay Saudi Arabia and the Gulf states of Bahrain, Kuwait, Oman, Qatar and the United Arab Emirates. Because of the intensity of the traffic between these countries and the Indian subcontinent and the vast annual pilgrimages to Mecca, the Consultation on the Worldwide Certification of Smallpox Eradication had recommended in October 1977 that WHO should obtain special country reports from each of them for review by the Global Commission in December 1978.

Iran, Iraq and the Syrian Arab Republic were not included in the Intensified Smallpox Eradication Programme in 1967 because they had eliminated endemic smallpox in 1963, 1959 and 1950, respectively. However, it was known that a major epidemic of variola major had spread through these countries in 1970-1972, after an importation from Afghanistan (see Chapter 23). Few of the many cases which occurred had been reported to WHO—29 from Iran in 1971 and 2 in 1972, 37 from Iraq, all in 1972, and 54 from the Syrian Arab Republic in 1972 (Fig. 26.10). Unofficial

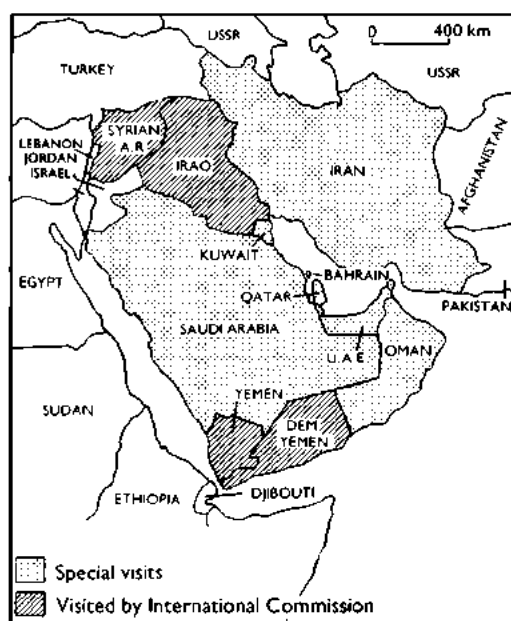

Fig. 26.9. Countries of south-western Asia and the Arabian Peninsula and the methods by which they were certified.

Fig. 26.10. Smallpox in Afghanistan, 1970–1977, and the 1970–1972 outbreak of smallpox in Iran, following an importation from Afghanistan. The disease spread to Iraq and the Syrian Arab Republic, and from Iraq to Yugoslavia. Numbers indicate the cases officially reported to WHO by month. In both Iran and Iraq, the numbers of cases which actually occurred and were known to the respective governments were far larger (see Chapter 23).

reports suggested that there was good reason to believe that transmission had persisted for almost 2 years in Iran, 8 months in Iraq and 4 months in the Syrian Arab Republic, with many more cases than had been reported.

The last cases of smallpox in these countries were believed to have occurred in 1972, some 5 years earlier but the Consultation believed that it was important to confirm with greater certainty that smallpox was not persisting in any of them and had not been present for at least the last 2 years. It therefore recommended that visits should be made to Iran, Iraq and the Syrian Arab Republic by Global Commission members, consultants and/or WHO staff, to verify and document smallpox eradication and present their findings to the meeting of the Global Commission in December 1978.

Certification did not proceed exactly as suggested by the Consultation. Iraq and the Syrian Arab Republic were visited and certified in succession by an international commission, of which the chairman, Dr Robert Netter, was a member of the Global Commission. In Iran, however, although extensive precertification activities were conducted, political events made it impossible to arrange the planned visit of an international commission to that country.

### Yemen

A WHO-assisted smallpox eradication programme had been initiated in Yemen in 1969 in the course of which the primary vaccina-

tion of 0.7 million children and the revaccination of 1 million persons, out of a population of 4.8 million, were carried out. Surveillance activities had discovered 23 possible smallpox cases between 1970 and 1977, but when specimens from these cases were examined in WHO collaborating centres no poxvirus particles were found.

In 1978 and 1979, a special search was conducted with the assistance of Mr Robert C. Steinglass, a WHO operations officer. This included the investigation of suspected cases of smallpox, the collection of specimens from every chickenpox outbreak discovered in the country, and facial pockmark and vaccination scar surveys in a large number of selected localities. Altogether 920 localities were visited in 146 of the 162 districts. The WHO reward of US\$1000 for information on new smallpox cases that could be confirmed was widely publicized to stimulate the reporting of suspected cases. In contrast to African countries, in which variola minor had been most recently endemic, variola major had been the prevalent form in Yemen, and a facial pockmark survey covering some 20% of the total population revealed 1920 pockmarked persons, all of whom were over 10 years of age (Table 26.16). None of them had had smallpox more recently than 1967. None of the 42 specimens collected from cases of fever with rash was found by WHO collaborating centres to contain poxvirus.

A vaccination scar survey revealed that only 22.9% of children aged 0–4 years had vaccination scars, a proportion that rose to 65.6% among those aged 5–9 years.

Table 26.16. Yemen: results of facial pockmark survey during active searches, 1978-1979

Governorate	Villages searched		Population of villages searched	Number of persons with facial pockmarks aged:		Year of the most recent infection
	Total number	Number where persons with facial pockmarks were found		0-9 years	≥ 10 years

Total	920	622	897 488	0	1 920	-

*Visit of the International Commission, 2-10 June 1979*

After preliminary discussions in Sana'a, the Commission members formed 3 teams and travelled widely throughout the country, except in the sparsely populated eastern desert area of the Marib, which was closed for political reasons. The results of the surveys confirmed those presented in the country report, and the Commission concluded that there was no evidence that there had been any endemic cases of smallpox since the last recorded cases in 1969. Accordingly, Yemen was certified to be smallpox-free.

### Democratic Yemen

Although Democratic Yemen had not reported a confirmed case of smallpox since 1961, the government undertook a smallpox eradication programme, beginning in 1970. In a mass vaccination campaign combining smallpox and BCG vaccinations, 4 mobile vaccination teams had performed 1.7 million smallpox vaccinations between 1970 and 1977, among a population of 1.7 million; 578 000 were primary vaccinations, and the take rate was over 90%.

#### *Precertification activities*

Special search operations were carried out between February 1978 and February 1979, with the assistance of a WHO epidemiologist, Dr Mohamed El Naggar. The offer of a reward of 50 Yemeni dinars (approximately US\$150) for the notification of a case of

smallpox was publicized by newspapers, radio and television. During a year-long operation, active searches were conducted in 55 of the 83 subdistricts in the country, including 2 subdistricts on the island of Socotra. Dr R.N. Basu and Dr Holger Lundbeck, members of the Global Commission, visited the country in November 1978 to study and advise on preparations for certification.

*Pockmark survey.* Facial pockmarks were seen only in persons over 14 years of age (Table 26.17). From the replies to questions put to those with pockmarks, it emerged that the most recent infection among them in Democratic Yemen had occurred in 1958. A vaccination scar survey recorded 59.8% with scars in the age group 0-4 years, the corresponding proportion reaching 96.9% in the age group 5-14 years. Of 36 specimens collected from cases of fever with rash during 1978-1979 and examined by WHO collaborating centres, 8 showed herpesvirus particles and none poxvirus.

*Visit by the International Commission, 3-11 June 1979*

After a briefing meeting in Aden, 3 teams, each including a Commission member, a WHO consultant and a national representative, visited 18 districts and carried out limited surveys for facial pockmarks (Table 26.17) and vaccination scars. The results obtained corroborated the evidence presented in the country report.

The Commission concluded that there was no evidence that the endemic transmission or importation of smallpox had occurred in Democratic Yemen since the smallpox eradi-

	International Commission	4 572	64 <sup>a</sup>

<sup>a</sup> Due to smallpox contracted before 1959.

cation programme had begun there in 1970. It certified the country to be free of smallpox.

#### Arab Countries of the Gulf Area: Bahrain, Kuwait, Oman, Qatar, Saudi Arabia, United Arab Emirates

The health services of these 6 countries had been greatly strengthened since the increase in income from oil production in the early 1970s. Indigenous transmission of smallpox was thought to have ceased in all of them in the 1960s, but there were numerous opportunities for importations to occur (see Chapter 23, Table 23.10) and the inadequacy of the surveillance system at that time meant that a report of zero incidence of smallpox could not be regarded as completely reliable.

The 1977 Consultation on the Worldwide Certification of Smallpox Eradication had therefore requested that detailed country reports should be supplied to the Global Commission (see Chapter 24).

One of the members of the Consultation, Dr Jalal M. Aashi, who was at the time Secretary-General of the Secretariat-General of Health for the Arab Countries of the Gulf Area, arranged for a member of the Smallpox Eradication unit, Dr Ehsan Shafa, to attend the meeting of the Secretariat-General in Riyadh, Saudi Arabia, from 30 October to 2 November 1977. Dr Aashi and Dr Shafa had drawn up a plan of action for the Gulf states, to be implemented during 1978, and this was approved by the assembled ministers of health. In fact the plan was more thorough than the Consultation's suggestions had indicated. Under its terms each country was requested: (1) to carry out chickenpox surveillance and collect specimens from selected cases; (2) to establish and maintain rumour registers of suspected cases of smallpox; (3) to carry out facial pockmark surveys; and (4) to prepare a country report. Specimen collection kits and forms for each section of the plan of action were provided.

Dr Arcot G. Rangaraj, a veteran of the smallpox eradication campaign in Afghanistan, was appointed as a WHO consultant for 6 months (1 March–31 August 1978) to help to implement the plan of action. He visited each country 3 times, contacting public health laboratories, hospitals, health centres and clinics, medical officers of oil companies, missionary and other private institutions, and private practitioners.

Table 26.18. Arab countries of the Gulf area: results of precertification investigations, January–July 1978

Country	Estimated population (1977)	Facial pockmark survey in children < 10 years old		History of children with facial pockmarks	Number of cases of chickenpox reported	Laboratory investigations <sup>a</sup>	
		Number examined	Number with pockmarks			Number of specimens tested	Number positive for herpesvirus
Bahrain	270 000	25 623	1	Contracted in Pakistan	3 154	50	16
Kuwait	1 130 000	80 791	0	—	1 766	78	35
Oman	810 000	67 060	1	9-year-old child, skin infection in infancy	480	39	10
Qatar	190 000	15 242	0	—	566	35	8
Saudi Arabia	7 630 000	158 075	0	—	831	105	46
United Arab Emirates	670 000	85 994	4	3, each infected 7 years earlier in Bangladesh, India and Pakistan; 1, a 9-year-old boy, infected in 1971 outbreak	1 871	52	32

<sup>a</sup> Specimens examined at WHO collaborating centres; all were negative for poxvirus.

The results of the special investigations are shown in Table 26.18. There was no evidence that smallpox had been present in any of the 6 countries since 1971.

After reviewing the excellent data provided in the reports of these countries, the Global Commission, meeting in December 1978, had no hesitation in certifying all of them to be free of smallpox.

## Iran

### *Preparations for certification*

Shortly after the Consultation in October 1977, Dr Shafa visited Iran from 2 to 14 December 1977, during which time, in collaboration with the health authorities, a plan of operations for the confirmation of smallpox eradication was prepared. In view of the large epidemic of smallpox in Iran in 1970-1972 (see Chapter 23), government health officials agreed to carry out a comprehensive programme. This was to last for 6 months, starting on 21 March 1978 (the Iranian New Year), and include: (1) chickenpox surveillance with the compulsory reporting of cases, and epidemiological and laboratory investigation of chickenpox outbreaks associated with deaths; (2) the maintenance of a rumour register and reports on the investigation of suspected cases of smallpox; (3) facial pockmark surveys; and (4) the preparation of a comprehensive country report.

Dr Parviz Rezai, Deputy Director-General of Communicable Diseases Control and Malaria Eradication, was put in charge of the programme, and by the end of February 1978 sanitary inspectors from every province in Iran, who were responsible for specimen collection, had attended a seminar in Teheran and been issued with specimen collection kits. A seminar was also held, attended by the chiefs of the communicable disease departments of all the provinces, to discuss the plan of action and their role in its execution.

Activities went on until 23 September. Dr Shafa continued to follow their progress closely and visited Iran again in August 1978. In October, he and Dr Lawrence Brilliant, who had worked as a WHO staff member in the smallpox eradication programme in India, visited Iran to assist in the analysis of the data and the preparation of the final report for the Global Commission. They also paid brief visits to the provinces of Ilam, Fars and Isfahan. It had been planned that Dr Aashi

and Henderson, members of the Global Commission, would visit Iran between 1 and 15 November, during which time they would be provided with a supplementary report giving epidemiological details of the 1970-1972 outbreak. However, their visit had to be cancelled owing to increasing civil unrest, which culminated in the deposition of the Shah and the proclamation of an Islamic Republic on 1 April 1979.

*Pockmark survey.* The object of the facial pockmark survey was to confirm the absence of smallpox during the previous 5 years (1973-1978); hence only children under 5 years of age were examined. The areas to be surveyed were selected in the following order of priority: (1) the environs of the last known smallpox outbreaks; (2) districts in which deaths from chickenpox had been reported; (3) districts in which suspected cases of smallpox had been reported; and (4) border territories and remote areas.

Of 72 337 children examined (1.2% of all those under the age of 5 years), 15 were reported to have apparent pockmarks. On investigation, the scarring was found to be due to chickenpox in 11 cases, to boils in 3 cases, and to the secondary infection of chickenpox vesicles in 1 case. The survey was conducted in 160 of the 162 districts, in all 23 provinces. Dr Brilliant visited the provinces of Fars and Isfahan during October 1978 and confirmed that the facial pockmark survey was well designed, the sampling frame was carefully chosen, and the survey procedures were understood by the health workers.

*Chickenpox surveillance.* Weekly reporting of chickenpox from each district by telegram was made compulsory for the 6-month period 21 March-23 September 1978. In all, 4076 cases were reported, giving an incidence of 12.2 per 100 000 population over a 6-month period, which was similar to incidence rates in other countries in which extensive chickenpox surveillance programmes had been undertaken. Of these reported cases, 88% were verified by senior health officials and epidemiologically analysed; 85% of the persons in question had vaccination scars. Laboratory specimens were taken from 46% of the 459 cases in unvaccinated subjects and from 140 chickenpox cases which, although the persons concerned had been vaccinated, were either severe or atypical or had occurred in an adult. Specimens were collected from every province except Boyer Ahmadi-ye Sardis va Kohkiluyeh, Kerman, Ilam, and Lorestan.

Ilam Province, which had reported the poorest chickenpox surveillance, was visited and checked by Dr Shafa in October 1978. All 349 specimens tested by WHO collaborating centres proved negative for poxvirus.

*Special investigation of suspected smallpox cases.* Four unusual cases of skin disease were investigated by physicians from the Communicable Disease Unit in Teheran. Two were found to be cases of molluscum contagiosum and the other 2 were severe chickenpox. Routinely, all cases of fever with rash were regarded as suspected cases of smallpox until proved otherwise by clinical, epidemiological and laboratory findings. Between 1973 and mid-1978, 309 such cases were investigated. All proved negative for variola virus on laboratory examination by the Pasteur Institute in Teheran, an establishment which had demonstrated a good laboratory capability for smallpox diagnosis in 1971-1972.

*Review by the Global Commission, 7 December 1978*

Dr Rezai presented a detailed country report entitled *Smallpox Eradication in Iran*, and Dr Brilliant an additional document, *The Special Programme to Confirm Smallpox Eradication in Iran*. In addition, 2 confidential reports—*Smallpox in Iran 1970-72*, prepared by the Iranian government, and *Smallpox in Fars Province, Iran, 1970-72*, prepared by Dr Brilliant—were made available to a special group of Commission members. These 4 reports provided very comprehensive data on the smallpox situation in Iran. The confidential government report gave details of 1996 cases of smallpox that had occurred in 400 outbreaks between November 1970 and September 1972 (see Chapter 23, Fig. 23.4), of which 1349 had been confirmed as positive for variola virus in the laboratory in Teheran.

The epidemic had originated from an importation from Afghanistan and was eventually controlled by mass vaccination. Its long duration (23 months) was due to the use of poor-quality liquid vaccine, and it was rapidly controlled as soon as potent freeze-dried vaccine became available (see Chapter 23). The political decision not to report the actual number of cases to WHO did not prevent the health services from being fully operational within the country and from being committed to eliminating the disease. There was no reason to believe that any cases had occurred after September 1972.

As has been mentioned above, political circumstances had led to the cancellation of the planned visit to Iran in November 1978 by members of the Global Commission, as recommended by the October 1977 Consultation, but on the detailed evidence before it the Global Commission had no hesitation in certifying that Iran was free of smallpox.

## Iraq

Smallpox had been eliminated from Iraq in 1959, so that there had been no WHO-assisted smallpox eradication programme in the country. Vaccination, and subsequently certification activities, were undertaken by the regular health services. Late in 1971, smallpox had spread from Iran to Iraq (see Fig. 26.10) but, as in Iran, the authorities had been reluctant to report it. Evidence obtained subsequently suggested that there had been at least 800 cases (see Chapter 23), but that the outbreak had been finally contained by June 1972.

*Preparations for certification*

In May 1978 Dr James Tulloch, a consultant with the Smallpox Eradication unit, visited Iraq to assist with the preparation of a country report and the organization of a facial pockmark survey. The basic report was prepared in collaboration with Dr Felix Jurji, the national Director of Epidemiology and Quarantine. In June, the Director-General of the Public Health Administration sent forms to all departments in the school health administration with a request that all schoolchildren should be examined for pockmarks and that the forms should be returned by mid-September for presentation to members of the International Commission, which planned to visit Iraq in October.

*Visit by the International Commission, 5-15 October 1978*

Because of the reluctance of the government to discuss the 1971-1972 epidemic, members of the Commission concentrated on determining whether Iraq had been free of smallpox for at least the previous 2 years. After a briefing meeting in Baghdad, Commission members and their colleagues formed 2 teams, which travelled widely through the country. They checked the quality of the

D.J.M. TARANTOLA, 1978

**Plate 26.6.** James Tulloch (b. 1949), an Australian epidemiologist who served as a consultant to the smallpox eradication programme from 1976 to 1980. He participated in the final stages of the eradication programme in Bangladesh and played an active role in preparations for certification in many countries.

reporting system, and visited hospitals, health units and the diagnostic laboratory in Baghdad. The general impression everywhere was one of competence. In the laboratory, 162 specimens collected between 1972 and 1978 from patients with a rash had been tested; all had proved negative for variola virus. Of these, 27 collected in January 1978 and 11 collected in March-June 1978 were tested in WHO collaborating centres, all with negative results.

Four out of 3825 children aged between 4 and 12 years who were examined had pockmarks, all due to smallpox contracted before or during 1972. Vaccination coverage was between 75% and 100% in primary-school children, depending on the area, and between 50% and 80% in preschool children.

The Commission concluded that there was no evidence that smallpox had occurred in Iraq since 1972 and that the health services were sufficiently reliable from the point of view of detecting, recording and reporting communicable diseases to ensure that, if a case of smallpox had occurred, it would have come to the notice of the central public health authorities. However, between their visit in October and the meeting of the Global Commission in December, the results of the facial pockmark survey had been received;

these showed that 17 out of 195 665 school-children had "facial pockmarks". No details were provided of the children's ages or of the dates on which they had suffered from smallpox. Certification was therefore delayed pending clarification of the situation. Subsequently, it was reported that, of these 17 children with "facial pockmarks", 16 had good primary vaccination scars, 15 cases were of chickenpox, 1 had had boils, and 1 had had another kind of skin infection. This information was sent to all Global Commission members in March 1979 and Iraq was certified to be smallpox-free by correspondence on 17 April 1979.

### Syrian Arab Republic

Because endemic smallpox had been eliminated from the Syrian Arab Republic in 1950, there had never been a smallpox eradication programme in the country. All vaccinations were carried out by the regular health services. The Iran-Iraq epidemic had spread to the Syrian Arab Republic in February 1972, but appeared to have been contained by May of that year (see Chapter 23).

#### *Preparations for certification*

After his visit to Iraq, Dr Tulloch proceeded to the Syrian Arab Republic in May 1978 to help to arrange the preparation of a country report, a facial pockmark survey and the collection of specimens for laboratory testing. Dr Nouri Ramzi, Vice-Minister of Health, arranged for Dr Tulloch to visit the area of the last outbreak, in which there were 54 reported cases around Meyadin in the south-eastern part of the country, along the Euphrates river, and on the main road from Baghdad (see Chapter 23, Fig. 23.5). A survey of 507 schoolchildren in this area found 15 with facial pockmarks due to smallpox, which made it clear that more cases had occurred than were notified in 1972, as well as revealing an unreported outbreak in the period 1966-1967. For the purposes of certification it was not considered worth while to make a major effort to clarify events which had taken place over 6 years before, but the government was asked to undertake a facial pockmark survey of the 6-year-old children entering school in September. If no pockmarks were found among them, that would be considered good evidence that no cases had occurred

since 1972. Surveys carried out on 28 072 6-year-old children in 197 schools in Damascus and 11 320 children in 207 schools in Deir-ez-Zor failed to find any pockmarks. The vaccination coverage was good in school-children in the higher grades—namely, 80–95%—and 50–60% among those in the first grade.

Since 1972, when 3 specimens taken from cases were found to contain variola virus by the WHO collaborating centre in Atlanta, USA, 1 specimen tested in 1974 had proved negative, as had 6 specimens tested by WHO collaborating centres between August and October 1978.

*Visit by the International Commission, 15–22 October 1978*

After reviewing data with the health authorities in Damascus, Commission members visited health centres and primary schools. Of 3873 children then examined, one had facial scarring reportedly due to smallpox contracted in Haffe in 1971. Four other persons with pockmarks were adults who had suffered from smallpox some 30 years previously. Commission members reviewed the reports and concluded that the detecting, recording and reporting of communicable diseases in the country were sufficiently reliable to ensure that, if an outbreak of smallpox had occurred since 1972, it would have come to the notice of the central public health authorities. Their recommendation that the Syrian Arab Republic should be certified to be free of smallpox was accepted by the Global Commission in December 1978.

### SOUTH-EASTERN ASIA

At the other side of the Asian land mass were several countries in which WHO-assisted smallpox eradication programmes had never been operative because the disease had been eliminated in 1962 or earlier. The largest country, China, is the subject of detailed consideration in Chapter 27. Malaysia had eliminated endemic smallpox by the end of 1949 and effectively controlled a large outbreak that had occurred after an importation in 1959 and continued into 1960. Singapore had reported no cases since a small outbreak following an importation in 1959. Both countries had had stable governments since 1960 and the Consultation did not

**Table 26.19. Thailand, Democratic Kampuchea, Lao People's Democratic Republic and Viet Nam: numbers of reported cases of smallpox, 1952–1963**

Year	Thailand	Democratic Kampuchea	Lao People's Democratic Republic	Viet Nam
1952	43	1 740	33	2 251
1953	50	1 788	15	1 582
1954	20	443	0	3 564
1955	117	483	0	1 907
1956	4	523	0	1 008
1957	3	125	0	472
1958	28	18	0	35
1959	1 548	4	0	13
1960	32	0	0	0
1961	33	0	0	0
1962	2	0	0	1
1963	0	0	0	0

recommend that any special investigation should be undertaken. The remaining 4 countries were Democratic Kampuchea, the Lao People's Democratic Republic, Thailand and Viet Nam; the numbers of reported cases of smallpox in these countries during the period 1952–1963 are shown in Table 26.19.

The October 1977 Consultation had recommended that, because of the prolonged hostilities and the possibility of breakdowns in the public health services, country reports should be obtained for Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam. The authorities of each of the countries concerned were to be asked to endorse these reports and, in so doing, to certify that no cases of smallpox had occurred in their country for the past 2 years. In view of the intense traffic between Thailand and India and Bangladesh, it was recommended that a member of the Global Commission or a WHO consultant should visit Thailand.

### Lao People's Democratic Republic and Viet Nam

In recommending that country reports should be obtained from Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam, the Consultation had taken a cautious attitude, for there had been only 1 reported case (in Viet Nam in 1962) since 1959. Because of the fighting there during the 1960s and 1970s, large numbers of foreign soldiers had been present in these countries, but no reports of the occurrence of smallpox

had been received. Furthermore, smallpox had been absent from neighbouring countries for many years, and over the past decade there had been little communication with the endemic countries of the Indian subcontinent.

Much of the available information on Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam was in the files of the WHO Regional Office for the Western Pacific in Manila, which requested these countries in March 1978 to provide additional information. However, by August of that year no reports had been received at WHO Headquarters in Geneva. To accelerate matters, Dr Bert van Ramshorst, a medical officer in the Smallpox Eradication unit, was sent to Manila on 4 October 1978 to prepare country reports, based on the data available in the regional office, for the Global Commission meeting early in December. These were sent to the respective governments for endorsement, which was eventually received in Geneva from Viet Nam on 28 November and from the Lao People's Democratic Republic on 29 November. Thus the Lao People's Democratic Republic and Viet Nam were certified by the Global Commission on the basis of the reports prepared from the documentation available in the regional office and the official statements by their respective governments that the countries were smallpox-free. However, the certification of Democratic Kampuchea had to be deferred, because government endorsement of the country report had not been received.

### **Democratic Kampuchea**

Formal endorsement by the government of Democratic Kampuchea of the country report prepared by the Smallpox Eradication unit proved to be very difficult to obtain because of the political turmoil in that country. Briefly, the situation was that, after a prolonged civil war, the Kampuchean National United Front for National Salvation took power in January 1979, overturning the Khmer Rouge government under Pol Pot and calling the country the People's Democratic Republic of Kampuchea. The Khmer Rouge fled, but continued to fight a guerrilla war against the new government, at the same time setting up, together with other groups, a rival coalition government. The latter was recog-

nized by the United Nations, so that official contact with the authorities who were actually running the country, necessary in order to obtain endorsement of the country report, was not possible.

In accordance with the decision that official government endorsement of the report was essential, the Global Commission, meeting in December 1978, deferred certification. During the succeeding months WHO took a number of steps designed to break the deadlock. These included attempting to make contact with the Ambassador of Democratic Kampuchea in Beijing and approaches via Dr Robert Netter, a member of the Global Commission resident in Paris, since at that time two French groups were working in Democratic Kampuchea, as were UNICEF and the International Committee of the Red Cross.

In early autumn news came that Dr My Samody from Phnom Penh was attending a meeting at the International Committee of the Red Cross in Geneva. He was contacted and given a copy of the report. At the same time an urgent request for the endorsement of the report was addressed to the government recognized by the United Nations through its mission in Geneva, but no reply was received.

On 8 November, a letter dated 25 October 1979 was received from Dr Nu Beng, Minister of Health of the People's Democratic Republic of Kampuchea in Phnom Penh, endorsing the country report and containing a declaration of the smallpox-free status of the country. This was accepted by the Global Commission, and together with China (see Chapter 27), Democratic Kampuchea was the last country in the world to be certified, on 9 December 1979.

### **Thailand**

In accordance with the recommendation of the October 1977 Consultation, Dr R. N. Basu, then Assistant Director-General of Health Services in India and a member of the Global Commission, visited Thailand from 8 to 27 May 1978 for an initial appraisal, field visits and the preparation of documentation. He visited Bangkok and 4 provinces, where he interviewed personnel in health offices, hospitals, clinics and schools, and also visited 2 refugee camps on the Laotian border. In the camps, he examined people for vaccination

scars, and by questioning them found that none had ever seen a case of smallpox either in the camp or in their country of origin. Dr Basu observed the way in which the communicable disease surveillance system operated in hospitals, in the 4 regional epidemiological offices, in the regional communicable disease control offices, and in remote areas, where mobile units were used for this purpose; he also evaluated the performance of the health volunteers scheme for providing primary health care at village level.

Documentation provided for the Global Commission included a comprehensive country report prepared by the government of Thailand and a paper presented by the government at the 1967 interregional seminar on smallpox eradication, which gave epidemiological details of the eradication of the disease in Thailand. The last case occurred in 1962—an importation from Calcutta, which did not give rise to any secondary cases.

On the basis of the country report and the evidence presented by Dr Basu, the Global

Commission in December 1978 certified that smallpox had been eliminated from Thailand.

## CONCLUSIONS

This complex series of operations, involving 29 countries in Africa and Asia over the brief period of 24 months, completed the certification of smallpox eradication in all the countries of the world in which the disease had been endemic in 1967, or countries otherwise regarded as at high risk, except for China and the countries of the Horn of Africa. Many different procedures were adopted, depending mainly on the prior history of smallpox and a variety of political considerations. There remained only the certification of China, the Horn of Africa and the adjacent country, Kenya, and the receipt from other Member States of WHO of certificates denoting freedom from smallpox for at least the preceding 2 years. These matters are discussed in the next chapter.

### INTRODUCTION

As the eradication of smallpox was certified, country by country and region by region, global certification activities finally focused on the Horn of Africa and China (Fig. 27.1). For very different reasons, these were the last regions of the world to provide the detailed information required before the global eradication of smallpox could be certified by the Global Commission in December 1979.

The Horn of Africa comprises 3 contiguous countries, Ethiopia, Somalia, and Djibouti (Fig. 27.2), in the first 2 of which smallpox had remained endemic after it had been eliminated from every other country in the world. The eradication programme in these countries had been hindered by warfare and civil disturbances (see Chapters 21 and 22), which continued into the period of precertification surveillance and of certification itself. The last known case of endemic smallpox in the world had occurred in Merca,

Somalia, in October 1977. In Kenya, smallpox was related epidemiologically to outbreaks in Ethiopia and Somalia because of the common borders with those countries, and the 4 countries were therefore grouped together for certification purposes. Furthermore, because of the movements of nomads and refugees between them, it was essential that all 4 countries should be prepared for certification and visited by international commissions simultaneously. A symbolic target date was established for the final certification, 26 October 1979—exactly 2 years after the onset of rash in the last case in Somalia.

In China, it was believed that the last case had occurred many years earlier, but WHO had not been involved in either the eradication campaign or any follow-up activities, nor did WHO officials have access to China before 1972. Even then, it proved very difficult to obtain a satisfactory description of how and when smallpox had been eradicated until a visit by a WHO team was arranged by the Smallpox Eradication unit in July 1979. Because of the vast population and size of China, the Global Commission believed that the smallpox situation there should be properly documented before its smallpox-free status could be certified.

### PREPARATIONS FOR THE CERTIFICATION OF SMALLPOX ERADICATION IN THE HORN OF AFRICA

With the global eradication of variola major in October 1975 and the imminent

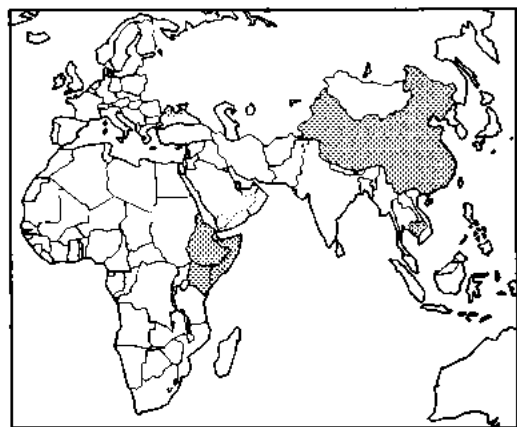

Fig. 27.1. The Horn of Africa, China and Democratic Kampuchea (see Chapter 26), the last areas in the world to be certified free of smallpox.

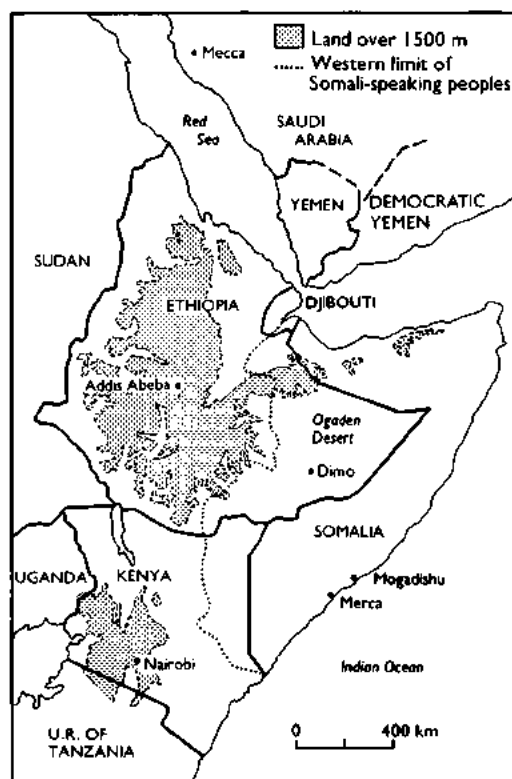

Fig. 27.2. The countries of the Horn of Africa and neighbouring parts of Africa and south-western Asia, showing land above 1500 metres. Dimo was the site of the last case of smallpox in Ethiopia, Merca that of the last case in Somalia.

eradication of variola minor during 1977, there was pressure to complete certification of the global eradication of smallpox as quickly as possible, because of its implications with respect to the discontinuation of routine vaccination and the abandonment of the requirement of vaccination certificates for international travellers. Because Ethiopia and Somalia were the last countries in the world in which smallpox had been endemic, it was possible to focus all available WHO resources on this effort, and from 1977 onwards much larger international resources were directed to these countries than had ever been made available to the other countries of Africa.

The problem of certification in the Horn of Africa was further compounded by the fact that the prevalent variety of smallpox had been variola minor, and studies in the area had shown that less than 10% of patients bore persistent facial scars after recovery. Thus pockmark surveys to determine whether smallpox had recently been present were of little use, and identifying cases of chickenpox,

which might have been confused with variola minor, and obtaining specimens from them for laboratory testing, therefore became of great importance.

### Coordination of Arrangements for Certification

In order to coordinate activities in the 4 countries and ensure that border areas were properly covered, the Smallpox Eradication unit organized a series of 3 coordination meetings. The first, in March 1977, was largely concerned with the completion of the eradication programme in Somalia and is described in Chapter 22; the second (September 1977) and third (April 1978) were devoted primarily to preparations for certification. Arita and Dr W. Koinange of Kenya undertook the laborious task of persuading sometimes reluctant governments to participate in these coordination activities.

#### *Second coordination meeting, Nairobi, September 1977*

In response to the emergency measures then in operation in Somalia (see Chapter 22), a second coordination meeting was held in Nairobi from 26 to 28 September 1977, 6 months after the first meeting, at a time when, as is now known, the interruption of transmission in Somalia was only a month away. It was attended by national smallpox eradication programme staff from Djibouti, Ethiopia, Kenya, Somalia, and the Sudan, together with WHO staff from the Smallpox Eradication unit and the WHO Regional Office for Africa. Despite the fact that, at the time, the Ethiopian Ogaden was occupied by the Somali army and the Western Somalia Liberation Front, a delegation from Ethiopia attended the meeting, exchanged information on surveillance activities with the participants from other countries and contributed greatly to the success of the meeting.

Discussions at the meeting were focused on how rapidly Somalia could eradicate smallpox and how the countries in the Horn of Africa could further strengthen their surveillance measures so as to prevent any further setbacks of the kind that had occurred in Somalia—namely, the establishment of new endemic foci following importations into smallpox-free areas. Important recommendations were made, among them the following:

"Smallpox surveillance activities, including specimen collection, should be increased in all priority areas of the participating countries for the next 12 months and, during this period, special attention should be paid to the possible presence of smallpox foci in both displaced populations and remote areas where search activities might have been incomplete or improperly conducted and vaccination coverage might be low.

"Special measures should be taken by all the participating countries to ensure appropriate vaccination and control of persons who travel abroad, especially those going to Saudi Arabia for the forthcoming pilgrimage. Somali medical teams going to Saudi Arabia for medical service of their pilgrims should be accompanied by experienced smallpox surveillance officers so that smallpox surveillance can be exercised during the pilgrimage period."

#### *Third coordination meeting, Nairobi, April 1978*

Since smallpox had not been reported from Somalia or elsewhere since October 1977, a third coordination meeting was held in Nairobi from 17 to 19 April 1978, specifically to discuss preparations for the certification of the Horn of Africa. It was planned that the meeting would be attended by programme staff from Democratic Yemen, Djibouti, Ethiopia, Kenya and Somalia, although at the last moment the delegates from Somalia were unable to attend owing to confusion about visas. Because of their proximity to Somalia, just across the Red Sea, it was originally intended that Yemen should also send representatives to this meeting. However, Democratic Yemen and Yemen were visited by international commissions and certified in June 1979, separately from the Horn of Africa (see Chapter 26).

The meeting decided that surveillance should continue at least until October 1979, in order to make sure that the Merca case had, in fact, been the world's last case of endemic smallpox. It was agreed that complete documentation on eradication programmes and precertification activities in the countries of the Horn of Africa should be submitted to the meeting of the Global Commission in December 1979, so as to allow it fully to appraise the progress of the programme and report its findings to the Thirty-third World Health Assembly in May 1980.

The meeting also requested WHO to offer a special reward to the first person to report an active case of smallpox anywhere in the world.

### Message from the Director-General of WHO

The historical significance of the third coordination meeting in the context of the global programme was well expressed by the message of the Director-General of WHO to the meeting:

"It is now almost six months since the last case of onset of rash was recorded in the Somali smallpox eradication programme. Since that date, 26 October 1977, no further case of smallpox infection has been detected in the Horn of Africa, or anywhere in the world. This date, therefore, appears to mark the turning point in the global smallpox eradication campaign. Until then, the major objective had been to eliminate all smallpox foci. But now the situation has changed. Now it is our task to demonstrate whether we have broken the chain of smallpox transmission which has continued amongst the peoples of the world for thousands of years.

"In this respect, this meeting has a special place in the history of smallpox eradication. Proving the absence of the disease is likely to be no less difficult than containing outbreaks. There will naturally be a certain degree of doubt, since the event has never happened before in the history of medicine.

"I believe this meeting will tackle the problem of scientific credibility fully and squarely. But one point is already made clear. Surveillance, once established on a sound technical basis, should continue throughout two years following the detection of the last case. This is the only way to ensure that the international criteria of public safety have been fully met.

"One of the most heartening aspects of the global eradication campaign is the way the countries concerned have worked together to achieve the enormous progress made to date. Your participation in this meeting again demonstrates that sense of international solidarity, and the desire of the six countries you represent to contribute to the goal of worldwide global eradication. The most critical programmes are those in your areas. The next two years' surveillance will mark the crucial phase in the final confirmation of this worldwide achievement."

Two weeks after the Nairobi meeting, the Thirty-first World Health Assembly did establish such a reward, the amount offered being US\$1000 (see Chapter 24).

#### *Precertification activities*

Intensive precertification programmes were undertaken in all 4 countries in preparation for visits by 4 separate international commissions in October 1979. The situation in each country was different. In Ethiopia and Somalia, the personnel and organization of the national eradication programmes were retained but shifted their target from the elimination of endemic foci to an active search for unreported cases. However, the ease with which these operations were accomplished differed greatly in the 2 countries. At the time, the whole of Somalia was under government control and the intensive surveillance activities developed during the eradication programme continued throughout the next 2 years. In the much larger country of Ethiopia, although active surveil-

lance could, with some difficulty, be carried out in most of the country, the Ogaden desert, which included portions of the 3 provinces of Bale, Hararge and Sidamo, was the scene of active warfare, with armed forces moving from Somalia into Ethiopia. These disturbances greatly increased the difficulties of active surveillance. The Ogaden was clearly an area of special concern, requiring particularly intensive surveillance because, as epidemiological studies there had shown, the transmission of variola minor could be sustained for many months among comparatively small population groups (see Chapter 22).

Endemic smallpox had been eliminated from Kenya in 1969, but some importations had occurred thereafter, most recently in December 1976, in a rural area adjacent to Somalia, so that a special surveillance programme in that part of the country had had to be organized. Similarly, Djibouti had had to organize special surveillance in 1977 because of its proximity to the Ogaden, whence refugees were flowing into the country.

### Precertification Activities in Ethiopia

The Ethiopian smallpox eradication programme was conducted successfully during a period of considerable political disturbance (see Chapter 21), which continued and indeed became more serious during the preparations for certification. Both the eradication campaign and the subsequent precertification operations are described in detail by Tekeste et al. (1984).

The last known case in Ethiopia occurred in August 1976 in Dimo village, El Kere *awraja*, in the Ogaden. There were then 25 WHO epidemiologists, 15 national coordinators and about 1000 Ethiopian staff in the smallpox eradication programme, using some 90 vehicles. From the end of 1976 onwards, Ato Yemane Tekeste served as the project manager of the Ethiopian smallpox eradication programme. He was assisted by 3 WHO epidemiologists (Dr Lev Khodakevich as senior adviser, Dr Claudio do Amaral and Dr Poerwokoesomo R. Arbani) and a WHO finance officer (Mr Omar S. Ismail). Under

Ato Tekeste's direction, 9 assessment officers supervised 15 programme coordinators, each responsible for one of the 15 regions, in the management, training and supervision of field staff as well as in the assessment of the programme. These coordinators employed a number of surveillance agents and intermediate supervisory staff, totalling about 1000.

With these changed staffing arrangements, the precertification activities were started early in 1977. During 1977, 1978 and 1979, when extensive searches for possible hidden foci were carried out, Eritrea as well as a number of other areas in the north and the Ogaden in the south were often partly or completely inaccessible because of civil disturbances and warfare. Accordingly, search operations were conducted or stopped as the areas became accessible or inaccessible. In border areas which became inaccessible to Ethiopian staff, rumours were investigated, wherever possible, from bases in Djibouti, northern Kenya and Somalia. This necessitated extensive coordination between the 4

countries through the exchange of reports on smallpox rumours, which was achieved by close contact between national programme directors and Arita, who frequently visited Ethiopia and the neighbouring countries.

#### *Political events in the Ogaden*

Because of military activities, precertification operations in areas under the control of the Ethiopian government were conducted differently from those in areas in which the government then had little control—namely Eritrea and the Ogaden (shown in Fig. 27.3 as a stippled area). Although the areas of limited access were geographically extensive, the majority of the population lived in the more accessible central highland areas. The last case of smallpox in Eritrea occurred late in 1972. Intensive searches in 1973–1974, before the activities of the separatist movement limited access to the rural areas, failed to reveal any evidence of further cases. The Ogaden desert, on the other hand, was the route by which smallpox had spread to Somalia in 1976 and was thus an area of great importance for surveillance.

Fig. 27.4 illustrates the changing fortunes of war in the Ogaden. Politically, the period of the smallpox epidemic in southern Somalia was marked at first by guerrilla activities in the Ogaden by the Western Somalia Liberation Front and then by the occupation of this area by the Somali army in July 1977. Eight months later the Ethiopian army recaptured the major towns, but continuing guerrilla activity prevented the resumption of normal surveillance elsewhere. By 1979 the situation had stabilized to the point where searches could be made along the western limits of the Ogaden.

#### *Precertification activities in the accessible areas*

Different parts of the politically accessible portion of Ethiopia presented somewhat different problems. Over most of the area routine surveillance was carried out through the newly established farmers' associations (see below) in the rural areas and urban dwellers' associations in the towns. In other areas special searches were organized. Certain areas were considered to be at high risk because the last cases had occurred there, access to them was difficult, or good routine

surveillance had not been possible. In others, travel was safe only during a few weeks of calm between outbreaks of civil strife. Finally, there were some remote, sparsely populated areas which had been infrequently searched and which could not be reached without special logistic arrangements or transport by helicopters.

*Searches in rural areas.* The population of Ethiopia is predominantly rural, only 11% living in towns or villages with 2000 or more inhabitants. The search for evidence of recent smallpox in most rural areas was based on the farmers' associations, which were co-operatives comprising some 500–1000 persons. There were about 20 000 of them in Ethiopia in 1977. Because of the close contact between members of these associations and their chairmen, it was possible to acquaint them with the need for reporting smallpox cases, and during the active search operations each association became a basic unit for the collection of information on smallpox.

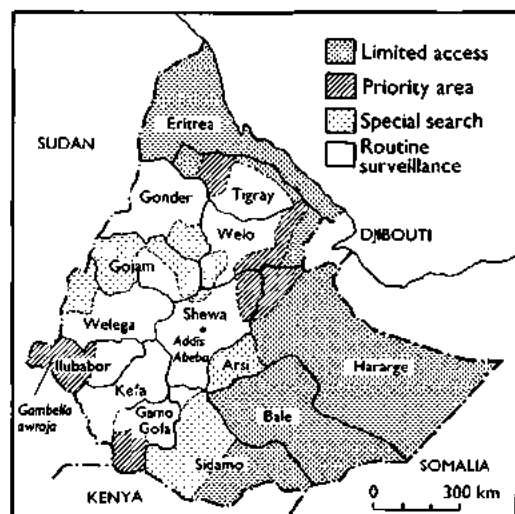

Fig. 27.3. Ethiopia: status of surveillance at the end of 1977. Throughout the programme, civil disturbances were occurring in various parts of the country so that smallpox staff were excluded from certain areas. Priority areas were defined as those difficult to reach, but where there was sometimes a calm period of a few weeks during which an intensive search could be carried out. Special searches were organized in areas which were in principle accessible, but where a satisfactory routine surveillance system could not be established. Routine surveillance was based on regular contacts with the 20 000 Farmers' Associations, whose membership accounted for two-thirds of the population of Ethiopia. For details of the search carried out in Gambella, Ilubabor, see box.

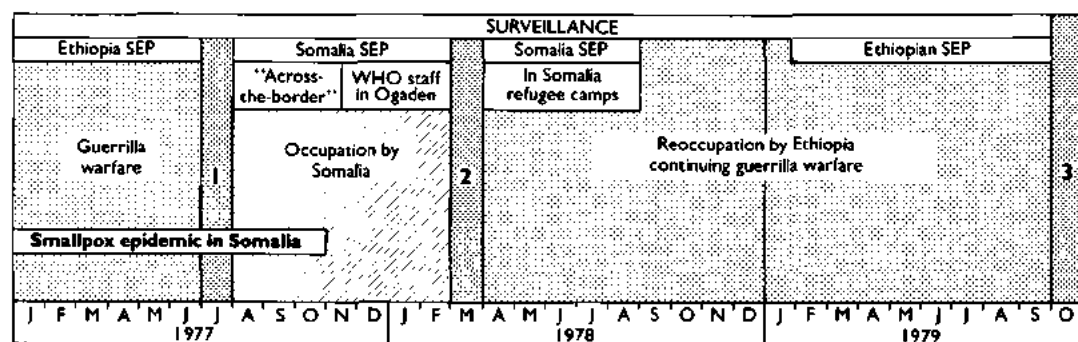

Fig. 27.4. Interplay between the changing fortunes of war in the Ogaden and smallpox surveillance activities. In July 1977 the Western Somalia Liberation Front overran the Ogaden and the Somali army established control (1). In March 1978, Ethiopian troops retook the Ogaden (2). Surveillance in varying degrees was maintained from both until eradication was certified in October 1979 (3). SEP = smallpox eradication programme.

During 1977, local surveillance teams were supposed to visit all the farmers' associations in their assigned areas 4 times a year. However, it soon became clear that coverage was erratic, 86% of the farmers' associations being visited at some time but some only once and many on several occasions. In 1978 this system was abandoned and a search for cases of smallpox was undertaken which covered some 50% of all houses in rural Ethiopia. Every month about one-fifth of all farmers' associations were visited by the surveillance workers. In this way, 20 322 out of the 20 828 farmers' associations were visited by surveillance workers between November 1978 and April 1979. The population thus contacted, either direct or through their neighbours, amounted to about 20 million—two-thirds of the total population of Ethiopia.

During the search the supervisors of the surveillance workers investigated 7260 cases of fever with rash and collected 929 specimens. A large number of cases of chickenpox and measles were seen, but no cases of smallpox.

*Searches in urban areas.* In addition to the searches in rural areas, the surveillance agents also searched urban areas during 1978 and 1979; thus 760 of the 929 towns, with a total population of 3.8 million, were searched, about 2500 cases of fever with rash being investigated and 189 specimens collected. Once again, no smallpox cases were found.

*Second visits to the sites of the last outbreaks.* During the period 1971–1976, smallpox had occurred in 99 of the 102 *awrajas* in Ethiopia. Between November 1978 and March 1979 the sites of the last outbreaks in 64 of these 99 *awrajas* were revisited by surveillance teams (Fig. 27.5). In the other 35 *awrajas*, mainly in

Eritrea and the Ogaden, no such follow-up visits could be arranged because of civil strife and the resettlement of the rural population. During the visits to these 64 *awrajas*, 2 additional outbreaks were identified which had occurred before August 1976, but there were no signs of transmission after the last recorded case.

*Laboratory investigations.* The variety of smallpox occurring in Ethiopia in the 1970s was variola minor, which elsewhere had been found to leave facial pockmarks in less than 10% of cases. As an alternative to pockmark surveys as a way of detecting missed cases of smallpox, special attention was devoted to the surveillance of chickenpox. Large-scale collections of specimens for laboratory

### Search in Gambella *Awraja*, Ilubabor Region

In Ethiopia, there were a few remote and inaccessible areas in which logistically it was extremely difficult to organize a search operation, Gambella *awraja* being one of them. This remote area (see Fig. 27.3) was inhabited mainly by primitive tribal groups. No smallpox had been reported there since the start of the eradication programme in 1971, but until 1978 the only search conducted was by a team consisting of an Ethiopian surveillance agent and a United States Peace Corps volunteer, who in April–May 1972 travelled by foot for about 290 kilometres along the Gilo river towards the Sudanese border to vaccinate and search for smallpox.

In March–April 1978, a well-planned search was conducted among the 140 000 inhabitants of this area. About 60 surveillance staff worked under the supervision of 2 Ethiopian coordinators and a WHO epidemiologist, Dr Claudio do Amaral, using helicopters and river transport. About two-thirds of all the houses in the *awraja* were visited by the team; the remainder had been abandoned because the people had moved close to the river, but the team visited them by walking along the river bank. In all, 36 suspected cases were investigated and 30 specimens were collected, but no smallpox was found.

investigation were made from cases of chickenpox or fever with rash, 2886 specimens being examined between 1977 and 1979 (Table 27.1). Fig. 27.6 shows the distribution, by *awraja*, of specimens collected during 1977 and 1978.

Variola virus was not found, but herpesvirus particles were seen in about 25% of the specimens and vaccinia virus on 9 occasions. The latter resulted from contamination, since specimens were sometimes collected while vaccinations were being performed.

*Precertification activities in the Ogaden desert*

The Ogaden desert, which traverses the major portion of the regions of Hararge, Bale and Sidamo (see Fig. 27.3), comprises 10 *awrajas* with a total population of about 1.4 million, most of whom are Somali-speaking nomads. It lies on a plateau bordered to the north and west by the Ethiopian highlands and to the south and east by Somalia, and by a small corner of Kenya in the extreme south-west. At its widest the desert extends 800 kilometres from east to west and 400 kilometres from north to south; it covers an area of about 200 000 square kilometres (Fig. 27.7). From the autumn of 1976 onwards the increasing guerrilla activities in the Ogaden made it more and more difficult for both WHO and Ethiopian programme staff to carry out surveillance; smallpox programme activities conducted by Ethiopian staff were finally halted in July 1977, when the Somali army invaded the area, but were resumed in

March 1978, when the Ethiopian army regained possession.

*Arrangements for surveillance.* To cope with this situation, Arita went to Addis Abeba in mid-1977 to discuss with local WHO and Ethiopian national programme staff how best to maintain active surveillance in the Ogaden. This was of the utmost importance, because the Western Somalia Liberation Front had overrun the area, so that it was inaccessible to the Ethiopian smallpox eradication programme staff. Moreover, at that time smallpox was still endemic in southern Somalia. There was therefore a real risk that endemic smallpox might be re-established in Ethiopia, and it was essential that this should be prevented.

Two major actions were therefore taken, one in Ethiopia and one in Somalia. First, in Ethiopia a "belt" area was established between the highland areas adjacent to the

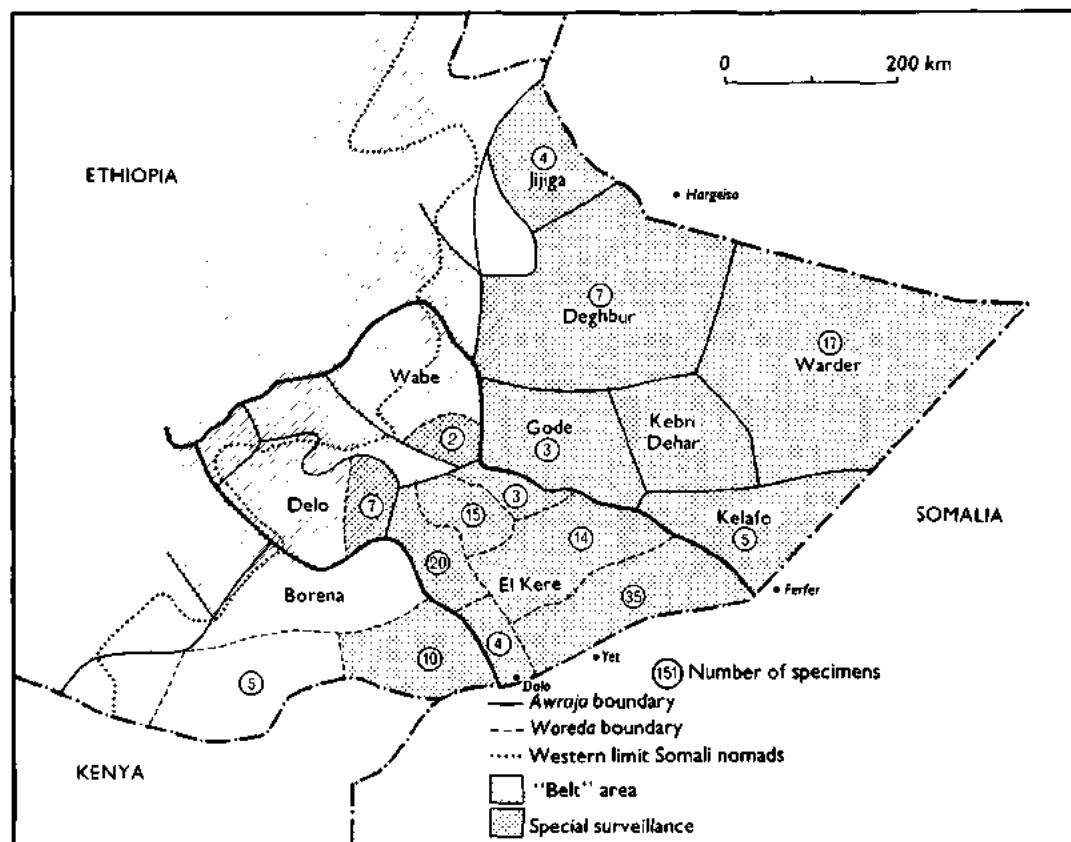

Fig. 27.7. Ethiopia: Areas of the Ogaden desert under special surveillance, showing *awrajas* in Hararge, Bale and Sidamo Regions, the western limits of the seasonal migrations of the Somali nomads, and the "belt" area where a special vaccination campaign was conducted in September-December 1977. The numbers of specimens collected for laboratory examination between July 1977 and April 1978 are shown by *awraja* and *woreda*.

### Surveillance Activities and the War in the Ogaden Desert

Early in 1977, the Ethiopian national smallpox eradication programme tried to strengthen surveillance by the assignment of 4 WHO epidemiologists (Dr do Amaral, Dr Arbani, Dr El Naggar and Dr Gromyko) and national coordinators. However, because of increasing unrest in the Ogaden, their activities were limited in scope outside the capital towns of the *awraja*s of Kebri Dehar, Deghbur, Warder, Kelafo, Gode and El Kere in the Ogaden desert (Fig. 27.7).

In April, Mr William Waugh, one of the helicopter pilots working for the Ethiopian smallpox eradication programme, was kidnapped at gunpoint and held for ransom near Gode. In May, Dr do Amaral was held for 2 days in Somalia when he came too close to the border while checking a rumour in Warder *awraja*. Again in June, he was kidnapped by guerrillas in Warder *awraja* but a week later turned up in Hargeisa in northern Somalia.

In June, immediately after this incident, WHO received a cable from the United Nations Economic Commission for Africa (ECA), Addis Abeba, stating that WHO epidemiologists were taking unacceptable risks. Arita flew to Addis Abeba to attend a meeting with ECA security officials to discuss the matter. It was agreed that the withdrawal of WHO epidemiologists would in fact mean the discontinuation of precertification activities, which would be a set-back not only for the eradication campaign in the Horn of Africa, but also for the global programme as a whole. The participants agreed that minimal activities should be continued by WHO and national staff in the Ogaden, but formulated a plan for emergency evacuation, should this prove necessary.

During the last 2 weeks of July, however, the Somali army invaded and overran the entire area, forcing the withdrawal of all the WHO staff. Thus, the surveillance of smallpox by the Ethiopian smallpox eradication programme ceased in these areas until March 1978, when the Ethiopian army resumed control.

Ogaden, which were under Ethiopian control, and the Ogaden desert, stretching from Djibouti to the border with Kenya (Fig. 27.7). An intensive surveillance and vaccination programme was carried out here between September and December 1977. On average, 55% of all farmers' associations were visited each month and by the end of the 4-month campaign, virtually all had been visited by a worker from the Ethiopian smallpox eradication programme. Altogether 348 suspected cases were investigated and 272 specimens collected, but no evidence of smallpox was found.

Secondly, an attempt was made to conduct an active search from the Somali side. Efforts to achieve this by collaboration with the International Committee of the Red Cross, which was doing relief work for wounded soldiers in the Somali-occupied areas of the Ogaden, were unsuccessful, but other arrangements succeeded.

Early in September 1977, Arita organized a private meeting in Mogadishu of senior WHO and Somali staff who had extensive experience of surveillance and knew the geography of the Ogaden. It was decided to

seek the agreement of the Western Somalia Liberation Front to enter the Ogaden and to employ 5 WHO epidemiologists, Dr Mohamed El Naggar, Dr Bert van Ramshorst, Dr Jean-Paul Ryst, Dr Jay S. Weisfeld and Mr Carl Hasselblad, to carry out across-the-border searches. Operational border posts were established in Hargeisa, Ferfer, Yet and Dolo (see Fig. 27.7). Many of the workers who had been employed in this area under the aegis of the Ethiopian smallpox eradication programme were recruited, because most had remained in the area after it had been occupied and were happy to return to duty. As the WHO epidemiologists could not cross the border into the area, which was under the control of the Somali army and the Western Somalia Liberation Front, experienced local workers supervised the searchers and verified rumours.

During these surveillance activities, 143 searchers visited 599 villages and 383 watering-places; 219 rumours were investigated. Posters giving information on the reward offered were displayed in each of the villages and at Koranic schools and watering-

places. The number of rumoured cases of smallpox was almost certainly exaggerated, as former Ethiopian staff had not been paid since the cessation of their programme in the area; by providing reports of possible cases of smallpox they assured their continued employment. In spite of the many suspected cases reported, experienced national epidemiologists found no evidence of continuing transmission.

In November 1977, Arita was informed by messenger that the Western Somalia Liberation Front had agreed that WHO staff could work in the Ogaden. Dr El Naggar, accompanied by a Somali counterpart, entered the Ogaden from Somalia to supervise surveillance personally and to check rumours. Because he was known to the local population, they cooperated closely with him. Borena and El Kere *awrajas* were chosen for the initial searches because they shared long borders with areas of southern Somalia in which smallpox had persisted until October 1977; furthermore, 11 of the 12 rumours of smallpox which had not been investigated by a WHO epidemiologist had originated in this area. Dr El Naggar supervised 20 searchers, who visited 33 000 houses and 300 Koranic schools. Independent assessment revealed that 94.6% of the houses had been visited by the searchers and that 51% of households knew

of the reward of 200 Somali shillings (US\$32). No smallpox was found.

In January 1978, Dr Rabie A. L. Khattab succeeded Dr El Naggar as the WHO epidemiologist responsible for surveillance in the Ogaden. He continued the programmes in Borena and El Kere *awrajas* and extended his activities to the adjacent *awrajas* of Dolo and Wabe. With the aid of 79 searchers, 20 000 houses and 700 Koranic schools were visited, but no evidence of smallpox was found. Surveillance from the Somali side was terminated early in March 1978, when Ethiopian forces reoccupied the Ogaden, but was then resumed under Ethiopian auspices.

**Laboratory investigations.** During special surveillance activities in the Ogaden between July 1977 and March 1978, 151 specimens were collected from cases of chickenpox or fever with rash and tested by WHO collaborating centres. The geographical distribution of the cases from which these specimens were collected is shown in Fig. 27.7. All the important areas in which smallpox importation or transmission was suspected were covered. Half the specimens were collected in El Kere *awraja*, the area in which the last known smallpox case in Ethiopia had occurred. Four of the 151 specimens were reported to contain small numbers of pox virions, as revealed by electron microscopy. Vaccinia virus was cultured from 2 of them, while the other 2 were negative. It was found that surveillance workers were using bifurcated needles that had been used for vaccination, to dislodge scabs, so that the positive results were presumably due to contamination with vaccinia virus. The source of 1 of the 2 specimens which was negative on culture was investigated by a WHO epidemiologist, who reported that, on clinical and epidemiological grounds, the case was definitely not smallpox. It was not possible to reinvestigate the patient from whom the fourth specimen had been taken. It was collected in July 1977 in El Kere *awraja*, but intensive and continuous search between August 1977 and March 1978 failed to find any smallpox in this area.

ologists, and about 1600 other personnel, using 65 vehicles, were engaged in surveillance and containment measures for the smallpox eradication campaign. Dr Abdullahi Deria, director of the national campaign, and Ježek, WHO coordinator, assisted by Mr Rodney J. Hatfield, WHO administrator, directed the campaign. This impressive force continued active search operations during 1978 and 1979, as required for certification, although the number of WHO epidemiologists was reduced to 10 by the end of 1977 as activities became better organized. The eradication campaign and subsequent precertification activities have been described in detail by Ježek et al. (1981).

#### *Development of reporting systems*

Apart from one person who was infected in southern Somalia in July 1977, but moved to a military camp in the north during the incubation period, all cases in the Somali epidemic had occurred in southern Somalia. The surveillance and containment programme had therefore been focused on that part of the country. With the conversion of the programme into post-eradication active search operations, routine reporting systems were developed throughout the country. To achieve this, a smallpox office was established in each of the 16 regions and 83 districts (Fig. 27.8).

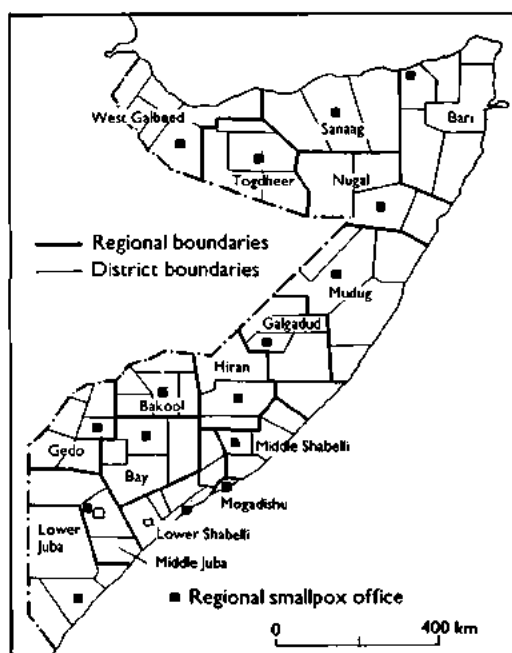

Fig. 27.8. Regions (named) and districts in Somalia. A smallpox office was established in each region and district during the period 1978–1979.

The regional smallpox offices were staffed by WHO or national epidemiologists and the district offices by local staff. They served to intensify the routine reporting of suspected cases of smallpox and other cases of fever with rash. A cable reporting findings was sent

Fig. 27.9. Somalia: Frequency of search operations for cases of fever with rash, by region. Partial searches were carried out by regional surveillance teams at hospitals and markets, and in high-risk areas. Most parts of the country were searched 6 times in 1978 and twice in 1979. In 1978 the full search procedure usually lasted a month but in 1979 less frequent searches allowed greater attention to detail and more thorough independent assessment of performance.

every week from each district to its respective region, and from there to Mogadishu. In addition to these reports, supplementary documentation was sent to Mogadishu describing the investigation of all suspected smallpox cases or deaths associated with fever with rash.

Although new to Somalia, this reporting system proved to be most effective, almost complete returns being received from all the smallpox offices. Regional and district offices gathered comprehensive demographic data including maps showing localities, house-

holds, population, etc., which were also used for other health programmes. These had to be updated frequently as the nomadic population moved from one part of the country to another.

#### *Search for cases of fever with rash*

The search for cases of fever with rash which had been developed during the smallpox epidemic in 1977 (see Chapter 22) was continued throughout 1978 and 1979. Six country-wide searches were conducted in 1978 and 3 in 1979. Except in the searches carried out during the first 3 months of 1978, all districts were covered (Fig. 27.9).

Following the pattern that had been developed in India, every search was assessed by national assessment teams, which found coverage to be very good (Fig. 27.10); over 70% of the general public reported that they had seen searchers with recognition cards and knew about the reward and where to report a case of suspected smallpox if they found one (Table 27.2). The high level of awareness among the nomadic population was impressive, since these people were rarely in contact with the established health services.

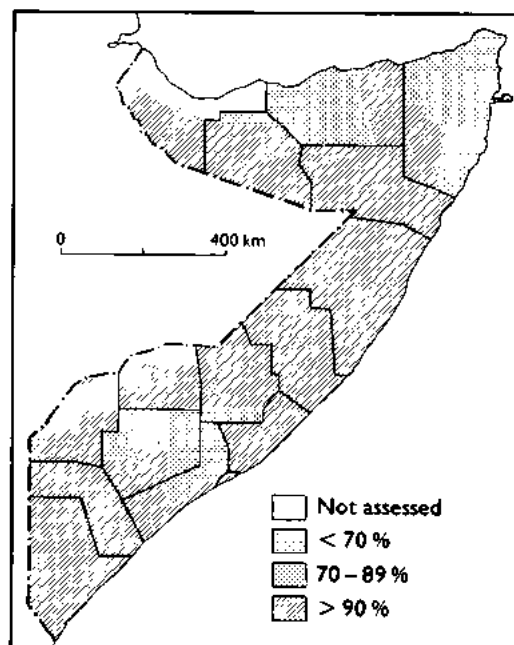

Fig. 27.10. Somalia national assessment of March 1979: percentages of localities found to have been searched in each district.

Table 27.3. Somalia: results of laboratory examinations of specimens submitted to WHO collaborating centres, 1977-1979

Year	Total number of specimens	Results			
		Variola virus	Herpesvirus	Vaccinia virus	Molluscum contagiosum virus
1977	879	265	203	1	0
1978	1 646	0	463	0	1
1979	1 074	0	214	1	0
Total	3 599	265	880	2	1

Fig. 27.11. Somalia: Number of cases of fever with rash reported monthly between January 1978 and September 1979.

In all, 19 623 cases of fever with rash were investigated in 1978 and 11 576 cases during the first 9 months of 1979 (Fig. 27.11). The diseases seen included chickenpox, measles and various other diseases associated with a rash; none proved to be smallpox.

#### Laboratory investigations

Laboratory specimens were collected from patients with clinically suspected smallpox and chickenpox, especially from those who had not been vaccinated, as well as from individuals affected in outbreaks of fever with rash in which a death had occurred.

Altogether 1646 specimens were collected in 1978 and 1074 in 1979, all of which were negative for variola virus (Table 27.3). Specimens were collected from all over Somalia, especially from the south (Fig. 27.12). The absence of variola virus in any of the specimens gave staff confidence that variola minor had not been misdiagnosed as chickenpox.

#### Precertification Activities in Kenya

Despite strenuous efforts, Kenyan and WHO epidemiologists had not been able to identify the geographical source of the outbreak of smallpox in Mandera District, northern Kenya, which occurred between December 1976 and February 1977, but it was thought to have been the result of importa-

tion from Somalia (see Chapter 19). During 1978 and 1979, searches in Kenya were conducted by staff recruited within the districts to be searched, and supervised by local health workers and senior health officers from the Division of Disease Control of the Ministry of Health, Nairobi. Dr W. Koinange, a Kenyan member of the Global Commission, Dr Ziaul Islam and Mr Vincent Radke contributed to the development of the Kenyan certification work. The Ministry of Health offered a reward of 200 Kenya shillings (US\$25) for any confirmed smallpox case, and the radio and press publicized the search operations and the need to report promptly any cases of fever with rash to the staff of the nearest health unit or to other government officials.

#### Special searches

High-risk areas were designated, essentially those bordering on Ethiopia and Somalia (Fig. 27.13), and special searches conducted in them. Searches were supervised at three levels: (1) by the public health technician (daily supervision); (2) by senior supervisors from the district headquarters; and (3) by independent assessment teams consisting of both national staff and their WHO counterparts working in the Division of Disease Control.

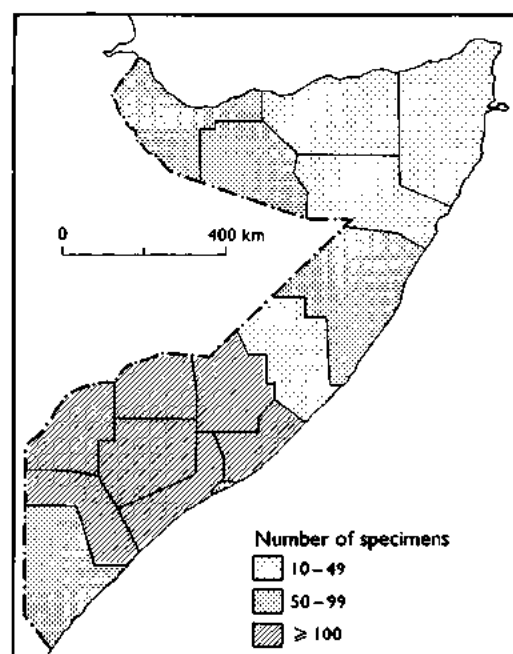

Fig. 27.12. Somalia: Number of specimens collected for laboratory examination from cases of fever with rash during 1978, by region.

The searches in the high-risk districts of Mandera, Wajir, Garissa and Marsabit were conducted between September 1977 and March 1978, 189 searchers and 43 supervisors, with 16 vehicles, being employed (Table 27.4). They covered over 440 000 persons in an area of 200 000 square kilometres.

In Mandera District, 6 searches were conducted, although occasionally some areas were not accessible to the local searchers and

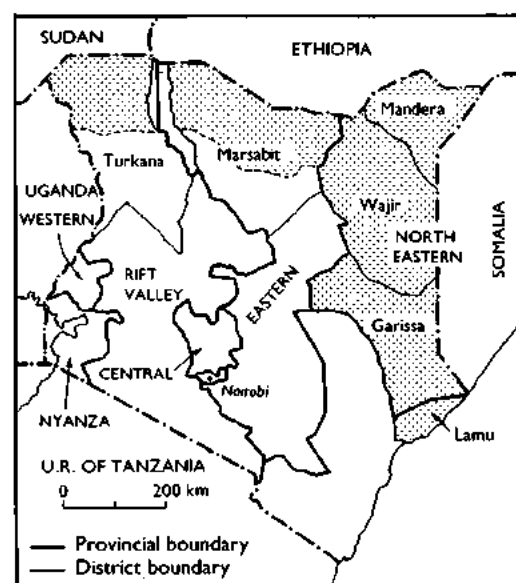

Fig. 27.13. Kenya: Areas of high priority for active search operations in 6 northern districts.

supervisory staff because of bad weather or for security reasons. Out of 134 rumours received only 2 could not be checked immediately because of security problems, but were checked later when the areas were visited.

In Wajir District, areas bordering on Ethiopia and Somalia were given priority in surveillance and vaccination activities. At the time, a large number of people had crossed from Ethiopia into northern Kenya to escape the conflict in the Ogaden and in search of water and grazing land. As rumours of smallpox from the Ethiopian side of the

**Plate 27.4.** Pilgrims' tents near Mecca in Saudi Arabia. The annual influx of people from the Muslim world provided an explosive potential for the spread of smallpox.

border came to the attention of Kenyan teams, they crossed the border to investigate whenever the security situation permitted. Five searches were conducted in the district and 35 rumours of possible cases were recorded. Only 3 rumours, all from the Ethiopian side of the border, could not be investigated because of security problems. However, cross-notifications were made to the Ethiopian health authorities through WHO in Geneva. Although Garissa District was not as important epidemiologically as Mandera and Wajir Districts, 4 searches were conducted there and 1 search in the northern area of Marsabit District.

A cluster sampling technique was used in assessing the search operations, 118 out of 120 localities sampled being assessed (98.3%) and 905 people interviewed. Of the latter, 72% reported that they had seen the searchers, and 75% had a smallpox vaccination scar.

#### *Laboratory investigations*

In 1978 and 1979, 1599 specimens were collected in high-risk areas and tested by WHO collaborating centres, with negative results.

#### **Precertification Activities in Djibouti**

Whenever famine or political unrest occurred in the Ogaden desert, many refugees fled to Djibouti. Between June and December 1977, when Somali troops invaded the Ethiopian Ogaden, some 10 000–20 000 refugees crossed into Djibouti, camping mainly in Djibouti City, Dikhil and Tadjoura.

On his return from the second Nairobi coordination meeting in September 1977, the representative of Djibouti, Dr A. A. Warsama, began work aimed at strengthening the local vaccination programme as well as surveillance for the detection of imported cases of smallpox. In November–December 1977, Dr Nicole Grasset visited Djibouti to work with the programme in conducting a special search for smallpox among the refugees. Dr Jean-Paul Ryst assisted the programme from September 1978 to October 1979 and Dr Arnaud Trébuq between May and December 1979.

The 1977 vaccination campaign reached 94 289 persons in Djibouti City, out of an estimated total population of 150 000. In December 1977, a vaccination scar survey of

1517 persons found 90% or more with scars in each age group.

#### *Active search operations*

Active search operations were planned in November 1977. The smallpox eradication programme activities were widely publicized, in particular the reward of 5000 Djibouti francs (US\$28) which would be given to anyone reporting a case of smallpox. An appeal from the President of the Republic to the population to collaborate actively with the programme and announcing the reward was published in the local press and read over the radio in Afar, Somali, Arabic and French. Any cases of fever with rash found during the search were to be reported to the supervisor or the Chief of the Department of Hygiene and Epidemiology on the same day. Refugees were vaccinated if they did not have a vaccination scar.

Full coverage of this small country was achieved in the course of 2 search operations, the first between December 1977 and January 1978 and the second between February and April 1978. In the second search, 20 chickenpox cases were found but no case of smallpox. Altogether 142 specimens were collected during 1978 and 1979 and tested by WHO collaborating centres; none contained variola virus.

#### **Smallpox Surveillance among Muslim Pilgrims from the Horn of Africa**

The pilgrimage season, during which over a million Muslims from about 40 countries visit the holy towns of Mecca and Medina, occurs in November–December. Even before the season starts, the number of international travellers to Saudi Arabia increases.

In 1977, the Saudi Arabian health authorities set up smallpox surveillance centres in Jeddah, Medina, Mecca, Mona and Arafat. A circular was sent to all medical groups concerned with the health problems of the pilgrims, indicating that any suspected case of smallpox should be promptly reported and investigated.

The Saudi Arabian health service checked all pilgrims on their arrival at ports of entry to ascertain whether they had an appropriate certificate of smallpox vaccination. Pilgrims from Djibouti, Ethiopia, Kenya and Somalia were examined to see whether they had vaccination scars. Pilgrims from Ethiopia and Somalia also had to submit particulars of their itinerary, intended address, the name of their guide, the name of the regions from which they came and whether they knew of any smallpox cases in their villages during the previous 3 months. Somali pilgrims were all vaccinated on arrival, regardless of their vaccination history, and the Somali govern-

Gromyko (WHO), Unidentified participant, Assefa Gobeze (Ethiopia).

ment sent smallpox surveillance teams to accompany the Somali pilgrims during their trip, to deal promptly with an outbreak should it occur. Foreign medical missions collaborated fully in these surveillance activities, making regular inquiries about cases of fever with rash. Saudi Arabian medical officers at Jeddah, Mecca and Medina visited Ethiopian and Somali camps at least twice a week. No case of smallpox was found. A total of 22 specimens collected from patients suffering from fever with rash were all negative. These activities were supervised by Dr Ehsan Shafa from the Smallpox Eradication unit, who worked in Saudi Arabia between 3 November and 9 December 1977.

### CERTIFICATION OF SMALLPOX ERADICATION IN THE HORN OF AFRICA

Since endemic smallpox had persisted in the Horn of Africa for many months after it had been eradicated from all other parts of the world, the certification of smallpox eradication in the countries concerned had important implications in terms of vaccination requirements throughout the world. The Smallpox Eradication unit therefore went to considerable trouble to organize certification activities and, believing that the last endemic countries could be certified by the commissions, prepared to publicize the event. Arrangements were made for all 4 countries to be visited simultaneously in October 1979 by separate international commissions, which would then meet in Nairobi to discuss their respective findings and announce the certification of smallpox eradication for the Horn of Africa as a whole on 26 October 1979, exactly 2 years after the recognition in Somalia of the world's last case of endemic smallpox. Arrangements were made in advance with representatives of the world media in order to ensure public recognition of the global eradication of smallpox.

By September 1979 each of the 4 countries concerned had prepared a comprehensive report on its national eradication programme and precertification activities. These reports were submitted in advance to the members of the respective international commissions before their visits. In order to coordinate arrangements, the chairmen of the 4 international commissions met at WHO Headquarters in Geneva and discussed the strategy

of their activities in each country and at the combined meeting in Nairobi. Prior to this, however, preliminary visits were made to Ethiopia.

### Preliminary Visits to Ethiopia

Two preliminary visits to Ethiopia by some Commission members were arranged, from 31 May to 15 June 1978 and from 3 to 18 April 1979, because Ethiopian certification involved some areas that were not fully under government control, and many high-priority areas were situated in regions in which travel was extremely difficult. The first visit, by Dr Keith Dumbell and Dr P. N. Shrestha, led to a joint decision by the Ethiopian government and WHO to carry out a single thorough search, instead of a multiplicity of searches, which were always incomplete and in fact beyond the capacity of the programme staff available.

In the second visit in April 1979, 7 commission members, of whom only Dr Jan Kostrzewski (chairman) and Dr Dumbell (rapporteur) also served on the final Ethiopian International Commission in October (see Chapter 24, Annex 24.1), went to Ethiopia. The group visited all the regions and 70 of the 102 *awrajas*, mainly in the highland areas, so that in October 1979 the final visit by

the International Commission would be able to concentrate on critical areas in the Ogaden (Fig. 27.14).

### Visits by the International Commissions

Separate international commissions visited the individual countries of the Horn of Africa during the first 3 weeks of October 1979, as follows:

	Date	Commission chairman
Djibouti	9-18 October 1979	Dr R. Netter
Ethiopia	1-17 October 1979	Dr J. Kostrzewski
Kenya	1-19 October 1979	Dr R. N. Basu
Somalia	1-21 October 1979	Dr H. Lundbeck

The 20 members of the 4 international commissions travelled extensively in their respective countries. In Ethiopia, because of the difficult terrain, a fixed-wing aircraft and helicopters were placed at the disposal of commission members, who used them to travel extensively throughout the country and to visit areas not accessible by overland travel. Since variola minor had been prevalent in these areas, the commissions paid special

attention to the laboratory investigation of 6671 specimens collected from cases of fever with rash in the 4 countries during 1978 and 1979; all proved to be negative for smallpox (Table 27.5).

In each country, the commission members were satisfied with the data presented on past surveillance activities and certified that the country concerned had been free of smallpox for at least the previous 2 years.

### Joint Meeting in Nairobi

After the certification of the individual countries had been completed, all members of the 4 international commissions and a number of others involved in the smallpox eradication programme, including 12 members of the Global Commission, some of whom had not been members of the international commissions, met in Nairobi, where the chairmen of the 4 commissions presented their respective reports. Having agreed that endemic smallpox no longer occurred in the Horn of Africa, and taking into consideration the recommendations presented in the reports of the 4 commissions, the joint meeting made the following recommendations:

(1) Smallpox vaccination should be terminated throughout Djibouti, Ethiopia, Kenya and Somalia.

(2) Vaccination certificates for smallpox should no longer be required of any travellers coming to, or leaving, the 4 countries.

(3) Experience from previously certified countries indicated that smallpox rumours would continue to occur even after certification. All such rumours were to be reported promptly to national authorities and thoroughly investigated by competent personnel, and the findings transmitted to WHO, so as to minimize unnecessary national and international concern. Specimens should be collected if necessary and sent through WHO, Geneva, to the WHO collaborating centres.

On 26 October 1979 a conference organized by the Smallpox Eradication unit was held in the Kenyatta Hall, Nairobi, in the presence of the Director-General of WHO, Dr Halfdan Mahler, the Regional Director for Africa, Dr Comlan A. A. Quenum, and the Regional Director for the Eastern Mediterranean, Dr Abdul H. Taba. Dr Kostrzewski, as the chairman of the joint meeting of the individual commissions, reported to Dr Mahler the commissions' conclusion that smallpox had been eradicated in the Horn of Africa. Immediately after this meeting, Dr Mahler sent the following message by cable or telex to all Member States and to international organizations:

"The Director-General of the World Health Organization presents his compliments and has the honour to ... inform you that International Commission today certified smallpox eradication in Horn of Africa which was last stronghold of disease Stop I personally believe smallpox has now been eradicated throughout world and am con-

fident that Global Commission for Certification of Smallpox Eradication will confirm this in December 1979 Stop I shall then present final report to World Health Assembly in May 1980 Stop World Health Organization has accomplished this mission with support and participation of all Member States"

On the same date, 26 October 1979, in the *Weekly epidemiological record*, health officials throughout the world were informed of the successful certification of smallpox eradication in the Horn of Africa (Plate 27.8).

The certification of the Horn of Africa meant that all countries in Africa had been certified. However, neither the Global Commission nor WHO was yet able to make a definitive statement on global eradication, since smallpox eradication in China had not yet been certified.

### CERTIFICATION OF SMALLPOX ERADICATION IN CHINA

After the Second World War, civil war broke out in the Republic of China. In October 1949, after the defeat of the Kuomintang government, the government of the People's Republic of China was established and controlled the whole of mainland China. However, the Kuomintang government, which controlled only Taiwan, was until 1971 recognized by the United Nations as having the right to represent the entire country. Obviously, the Kuomintang government was unable to provide WHO with data about smallpox on the mainland. WHO was therefore not in a position to receive information on mainland China until 1972, when it followed the policy of the United Nations and recognized the government of the People's Republic of China as the only government having the right to represent China.

### Lack of Information on Smallpox Eradication

Although mainland China was in theory accessible to WHO representatives from 1972 onwards, for several years it was very difficult to obtain information on health matters. From the outset of the global eradication programme, the Organization was understandably concerned about the smallpox situation in the most populous country in the world. Discussions in Geneva with Dr Chang

to

26 October 1979

2

YEARS / ANS

### SANS VARIOLE

26 octobre 1977

au

26 octobre 1979

Exactly two years to the day have elapsed since this man fell ill with smallpox in the town of Merca in southern Somalia. He is the world's last known case of endemic smallpox.

The basic criterion for confirming the eradication of smallpox is that two years must have elapsed without a case of smallpox being detected by a system of surveillance sufficiently sensitive to have detected a case had it occurred.<sup>1</sup> This criterion has now been met. The evidence will be subjected to critical review by a panel of experts, the Global Commission for the Certification of Smallpox Eradication. Their report will be the basis of a presentation to the World Health Assembly in May 1980. The endorsement of eradication will signify formal recognition that routine smallpox vaccination and vaccination certificates are unnecessary. The risk of complications from vaccination is obviously greater than the risk of getting smallpox, which is now zero.

Deux années exactement se sont écoulées depuis que cet homme a contracté la variole dans la ville de Merca en Somalie du Sud. Il s'agit du dernier cas connu au monde de variole endémique.

Le critère fondamental de confirmation d'éradication de la variole est que deux années se soient écoulées sans qu'un cas de variole ait été détecté par un système de surveillance suffisamment sensible pour avoir pu détecter tout cas qui se serait produit.<sup>1</sup> Cette condition se trouve maintenant remplie. Les pièces du dossier feront l'objet d'un bilan critique de la part d'un groupe d'experts, à savoir la Commission mondiale pour la Certification de l'Éradication de la Variole. Le rapport de cette Commission servira de base à un exposé qui sera présenté à l'Assemblée mondiale de la Santé en mai 1980. L'enregistrement de l'état d'éradication apportera la confirmation officielle que la vaccination antivariolique systématique et l'exigence de la production de certificats de vaccination n'ont plus de raison d'être. Le risque de complications vaccinales est de toute évidence plus grand que le risque de contracter la variole, qui est devenu nul.

**Plate 27.8.** Cover of the *Weekly Epidemiological Record* for 26 October 1979, the day on which certification of the Horn of Africa was completed in Nairobi. The illustration shows Ali Maow Maalin, who was diagnosed as having variola minor on 26 October 1977 and was the last case in the world of endemic smallpox.

Wei-hsun, an Assistant Director-General of WHO, who was a paediatrician from Beijing, elicited the information that he had not seen a case of smallpox since 1957 and was unaware of cases anywhere in China after about 1960.

In the absence of better ways of obtaining information, two other approaches were adopted. Whenever possible, Henderson and Arita met individuals or delegations planning to visit China and told them that the Smallpox Eradication unit wished to obtain more definite information about smallpox in China. They were asked to look for facial pockmarks wherever they went and to estimate the age of any person with such pockmarks. About 15 reports were received on facial pockmarks seen in China, but without exception the persons concerned were adults—no pockmarked children were seen.

Another approach was to examine refugees from China after they had crossed the border into Hong Kong and Nepal. Arita visited Hong Kong in 1970 to request the local authorities to conduct a pockmark survey. However, although the Hong Kong health authorities originally agreed to do so, they subsequently declined, feeling that it was a politically sensitive matter. In 1975, Dr P. N. Shrestha, director of the national smallpox eradication programme in Nepal, conducted pockmark surveys among Tibetan refugees in that country, and found that 43 out of 2350 of them (1.8%) had facial pockmarks. Although they could not remember exactly when they had had smallpox, none of these people recollected that it had been contracted later than 1961 and none was less than 14 years old in 1975. The results suggested that smallpox had been eradicated in Tibet early in the 1960s.

The Consultation on the Worldwide Certification of Smallpox Eradication, held in October 1977, devoted some time to discussing the smallpox situation in China. It considered that, although according to the information available it seemed unlikely that smallpox was still endemic there, China's vast size and population—one-quarter of the world's total—justified a more detailed study. For this purpose, the Commission recommended that during 1978 China should be visited by an international commission, WHO consultants or WHO staff, to verify and document its history of smallpox eradication. This was eventually achieved in July 1979.

The problem was one of effective communications. Chinese officials, on the one hand, felt that additional documentation and a visit by Commission members were unnecessary, as transmission had been interrupted many years earlier; the Commission, on the other hand, believed that the available documentation from China was not sufficient to convince the world community of the reality of this achievement.

Because of the difficulty of obtaining the requisite information, China was (with Democratic Kampuchea, see Chapter 26) the last country to be certified by the Global Commission as being free of endemic smallpox, on 9 December 1979.

### Development of Effective Contacts with China

#### *Initial efforts, 1973–1976*

At the Twenty-sixth World Health Assembly, in May 1973, the delegate from China reported that smallpox eradication had been achieved in practice by 1959 through a country-wide vaccination campaign initiated following Liberation (World Health Organization, 1973b). Extensive use had been made of part-time vaccinators and health auxiliaries in order to cover remote areas adequately. Once vaccination of the population had been completed, smallpox control had been integrated into the general health services and everyone was routinely vaccinated and revaccinated every 6 years. This had been reinforced by the recent growth of health cooperatives and the "barefoot doctor" system. No other details were given. Information on the health system in China began to emerge with the WHO study visits in 1973 and 1974, but none of these provided any specific details about smallpox, nor was there any assurance that importations from endemic neighbours to the south (Bhutan, India and Nepal) would be quickly detected and contained.

#### *1977: Increasing urgency of better contacts*

In January 1977 WHO was still no better informed about the eradication of smallpox in China and was beginning to consider seriously how to approach the problem of certification. A representative of China was invited to serve on the International Commission for the

Certification of Smallpox Eradication in Bangladesh and Burma in November–December 1977, in the expectation that the Chinese authorities might be interested in determining whether China's southern neighbours were free of smallpox. However, an invitation sent in May 1977 was declined on the grounds of "busy working arrangements". A separate invitation to participate in the October 1977 Consultation on Worldwide Certification was also refused, despite the personal attention of Dr Ch'en Wen-chieh, the Chinese Assistant Director-General of WHO who had succeeded Dr Chang Wei-hsun.

Following a request from the Smallpox Eradication unit, the WHO Regional Office for the Western Pacific cabled Beijing on 26 September 1977 and requested a brief summary statement covering the date of the last case, ongoing surveillance activities, vaccination policy and information on laboratory stocks of variola virus. The reply sent on 24 October 1977 was, if anything, briefer than the statement made by the Chinese delegation at the World Health Assembly in 1973, except that the information was given that variola virus was being held by specific institutions designated by the government. The reaction of the Chinese seemed to be one of indifference to the opinion of the rest of the world. They seemed to feel that no one need doubt their word that smallpox had been eliminated from China many years earlier.

Predictably, the Consultation in October 1977 recommended that WHO should obtain more information from China and that a visit should be arranged for a group which would include members of the Global Commission.

#### *1978: Further informal contacts*

On 4 January 1978, a letter was sent from the Regional Office for the Western Pacific proposing that 3 international experts and 3 WHO medical officers should visit China for 3 weeks during July–August 1978, and pointing out that "smallpox eradication in China appears to have been uniquely successful in terms of the vast geographical areas and methods employed. Detailed information on these activities would be of considerable value when worldwide eradication is reported to all Member States of WHO at the World Health Assembly". In order to make the proposal more readily acceptable a list of 6 experts and 5 WHO epidemiologists was attached to

the letter, to enable the Chinese government to make a choice.

On 28 February 1978, following the adoption by the Executive Board of a resolution requesting the Director-General to establish the Global Commission for the Certification of Smallpox Eradication, the Chinese government was invited to nominate a member of the Commission. In their reply of 29 April, the Chinese authorities again declined to become involved in the certification process. At the same time a brief reply was received to the letter of 4 January from the Regional Office for the Western Pacific reiterating what had been stated previously concerning smallpox and adding:

"It is based on the principle of responsibility for the health of the Chinese people and the people of the world and on the conscientious and careful conclusion reached after long years of thorough investigation and scientific surveillance that the Chinese Government has declared smallpox eradicated. As to the proposed visit to China by a group including members of the Global Commission with a purpose to 'certify' whether or not China has really achieved smallpox eradication ... I regret such a visit could not be arranged."

It was obvious that more effective communications were required between China and WHO on the philosophy of the certification programme. During the Thirty-first World Health Assembly, in May 1978, informal discussions were held between Dr Hsueh Kung-cho and other members of the Chinese delegation and WHO officials, including Arita, Chief of the Smallpox Eradication unit, at which it was agreed that the proposed visit should be postponed and that China would prepare a country report for the Global Commission before any further steps were taken. There followed a prolonged series of informal contacts aimed at convincing the Chinese authorities that the requests by WHO for more information and the invitations to participate in the certification commissions did not imply that WHO doubted their word that smallpox eradication had been achieved, but rather that it was a matter of compiling formal documentation which would convince health authorities all over the world so that it would be possible to discontinue smallpox vaccination everywhere.

Informal approaches were made during the visits to China by Dr William Foege, Director of the Center for Disease Control, Atlanta, USA, in June 1978 and by Mr Paul Lawton,

**Record of the Exchange of Views at an Informal Meeting in May 1978 (I. Arita)**

"Dr Hsueh Kung-cho first explained the smallpox situation in China. In 1950, special regulations to deal with the smallpox problem were set up and an eradication programme started. In 1959 the last case was recorded and to date there have been no further smallpox cases detected. Notably during the last ten years, national health programmes have been further strengthened, establishing close communication at province, country and town levels.

"I [Arita] explained the following points: Although I personally believed that smallpox had been eradicated in China, data to support this achievement were not sufficient. In the context of certification activities for global smallpox eradication, there are still a considerable number of health personnel as well as the press community who express uncertainty regarding smallpox in China. It is most desirable therefore for China to show their achievement to the world.

"In reply to this, Dr Hsueh Kung-cho indicated that a country report on surveillance activities for smallpox eradication would be prepared by China and submitted to WHO and all other necessary action required would be further reviewed when this report was prepared. In the circumstances, it was agreed that the initial proposal from WHO for Global Commission members to visit China during July-August 1978 should be postponed.

"The timing of the certification activities was discussed. The first Global Commission meeting would take place in December 1978 and the final meeting was expected to take place in October or November 1979, so that preparation of the report had to be started as soon as possible. It was agreed that the Smallpox Eradication unit would submit items to be included for special documentation during the next few days."

Division of Coordination, WHO, in October 1978. No concrete results were obtained, but the impression was gained that the Chinese authorities were becoming more open and responsive.

On 27 November 1978 WHO received a 2-page document entitled *A General Introduction on the Eradication of Smallpox in the People's Republic of China*, from Dr Chiang Yi-chen, Minister of Public Health. The only new information was that the last case had occurred in March 1960 in Yunnan Province and that variola virus was held by the National Institute for the Control of Drugs and Biological Products in Beijing.

During the meeting of the Global Commission in December 1978, Arita organized a special subcommittee to discuss this report and future plans for the certification of China, the participants being Fenner, Chairman of the Global Commission; Dr Foege, who had recently visited China; Henderson, former Chief of the Smallpox Eradication unit; Dr Kostrzewski, who had been Chairman of the International Commission for the Certification of Smallpox Eradication in India; and Dr Shrestha, who had organized the

pockmark survey of Tibetan refugees in Nepal. The unanimous opinion of the subcommittee was that it was highly likely that smallpox had been eradicated in China, in view of the structure of the health and social services in the country, but that evidence was lacking; that high-level negotiations between China and WHO or influential WHO Member States on behalf of WHO would be required to obtain data; and that technically the minimum data requirement would include the results of surveys for facial pockmarks and vaccinations scars on a province-by-province basis. Dr Kostrzewski stressed the desirability of oral negotiations at the stage that had been reached; continued written requests might be perceived as intimidating. The subcommittee drafted a statement which was approved by the plenary meeting of the Global Commission and included in the Commission's report for 1978:

"Considering the extensive health service network in China and its capability for effective surveillance, the Commission expressed confidence that smallpox transmission had been interrupted. However, it was believed that more

substantial documentation would be of considerable importance to provide persuasive evidence of this fact to the world community. A more complete country report should be sought with information presented, if possible, on a province-by-province basis. Useful information would include documentation of the last cases, an account of past smallpox activities in individual provinces and current epidemiological surveillance activities indicating how suspected cases would be detected. Certification of freedom from smallpox was deferred pending receipt of additional information."

During 1978, the Global Commission certified a number of countries, including Namibia, Southern Rhodesia (Zimbabwe), and Thailand, but deferred certification of China, Democratic Kampuchea, Iraq, Madagascar and South Africa because of insufficient evidence.

*1979: A visit by a WHO team is arranged*

The next initiative in what had become rather delicate negotiations was undertaken, at WHO's request, by Sir Gustav Nossal, Chairman of the WHO Western Pacific Advisory Committee for Medical Research, who visited China in April 1979. He engaged

in informal discussions to find out under what conditions the Chinese would accept a visit by Fenner (a fellow Australian who was Chairman of the Global Commission), accompanied by a WHO staff member. The response was encouraging. He detected a positive and flexible attitude on the part of the Chinese, who showed far less sensitivity to the issue than he had expected. The proposed visit appeared to be welcome. During the Thirty-second World Health Assembly, in May 1979, information was provided informally to the effect that the Chinese would agree to a visit by Fenner in July.

*Visit of the WHO team to China*

The result of these protracted negotiations was that a WHO team consisting of Fenner and Dr Joel Breman, of the Smallpox Eradication unit, visited China from 14 to 30 July 1979. They found that a country report had already been prepared by Professor Jiang Yutu, Professor Li Heming and Dr Zhao Kai, three scientists who had participated in a meeting of officials from laboratories retaining variola virus and the national control authorities concerned, which had been held

BY COURTESY OF J. BREMAN

**Plate 27.9.** The WHO team of J. Breman and F. Fenner, in Kunming, Yunnan Province, China, with Fu Guichen, Jiang Yutu, Jiang Weizhang and Zuo Kejia. Jiang Yutu accompanied the WHO team; the other Chinese were health officials of Yunnan Province.

### The Improvement of Health Services in China

Immediately after the Liberation, one of the first acts of Mao Zedong's government was to eliminate smallpox from China by mass vaccination campaigns. This was achieved by enlisting community support and using all available health personnel for intensive vaccination campaigns (see Chapter 8). Later, routine vaccination was incorporated into primary health care. Although there had been undeniable improvements since 1949, in the early 1960s health services were still not being provided to many of the 85% of the population living in the rural areas. Mao Zedong's directive of 26 June 1965 prescribed that, in health and medical work, the stress should be put on the rural areas. The changes made were: (1) the establishment of mobile medical teams formed out of existing health manpower to work in the rural areas; (2) the discontinuation of formal medical education pending its complete reform; (3) the genuine unification of traditional and western medicine; and (4) the massive training of "barefoot doctors" and health auxiliaries for the delivery of health services to the rural population.

The Ministry of Health was reorganized and responsibility for the delivery of health services delegated to the provincial, regional or municipal level. At the same time, five-sixths of the state bureaucracy in Peking was disbanded. As a consequence of this radical decentralization, emphasis was given to the rural areas and by 1974 satisfactory coverage of the entire population had been achieved. This, however, also had the result that there was little or no epidemiological information on a country-wide basis at national level. On the other hand, comprehensive information was available at provincial and commune level.

Awareness of the need to report communicable diseases was highly developed and coverage in terms of surveillance very extensive, as even in production teams—the basic units of community organization—one person was made responsible for disease notification.

in Geneva from 23 to 24 April 1979. As others had predicted, once discussions had been established on a person-to-person basis, matters went very smoothly. The WHO team reviewed the report with the authorities as well as a special detailed report on the last outbreaks in Yunnan Province. This report also included the results of a vaccination scar and pockmark survey of 73 820 persons in the border areas of Yunnan carried out in March–May 1979. Their only real concern at the time was that, while there was comprehensive information concerning the last cases reported from Yunnan in 1960, cases had also been reported in Xizang Autonomous Region (Tibet) in 1960, about which there were no details. It was impracticable for the WHO team to visit Xizang, but the Chinese authorities promised to carry out investigations comparable to those described for Yunnan.

The WHO team, accompanied by Dr Jiang Yutu, examined the communicable disease surveillance system in three areas: Beijing municipality, Shanghai municipality and Yunnan Province, from which the last endemic case in China has been reported in 1961 (Fig. 27.15). In all areas, visits were made

to provincial, municipal and district epidemic prevention sections, commune hospitals, health centres, and village primary schools. The team was impressed by the detailed records available at provincial and municipal level about smallpox outbreaks and vaccination campaigns which had been conducted well over 20 years previously. Fenner and Dr Breman felt confident that the system for the surveillance of communicable diseases operating in the country would have detected outbreaks of smallpox if they had occurred after 1960.

It was also agreed that 2 representatives from China would participate in the December meeting of the Global Commission in 1979, one of whom would be a member of the Global Commission and the other an epidemiologist familiar with the details of the eradication of smallpox in China.

The WHO team's visit as well as communications between China and WHO resulted in several documents becoming available on smallpox eradication in China, containing a great deal of data completely unknown to WHO and to the world scientific community before 1978 (WHO/SE/79.142 Rev. 1;

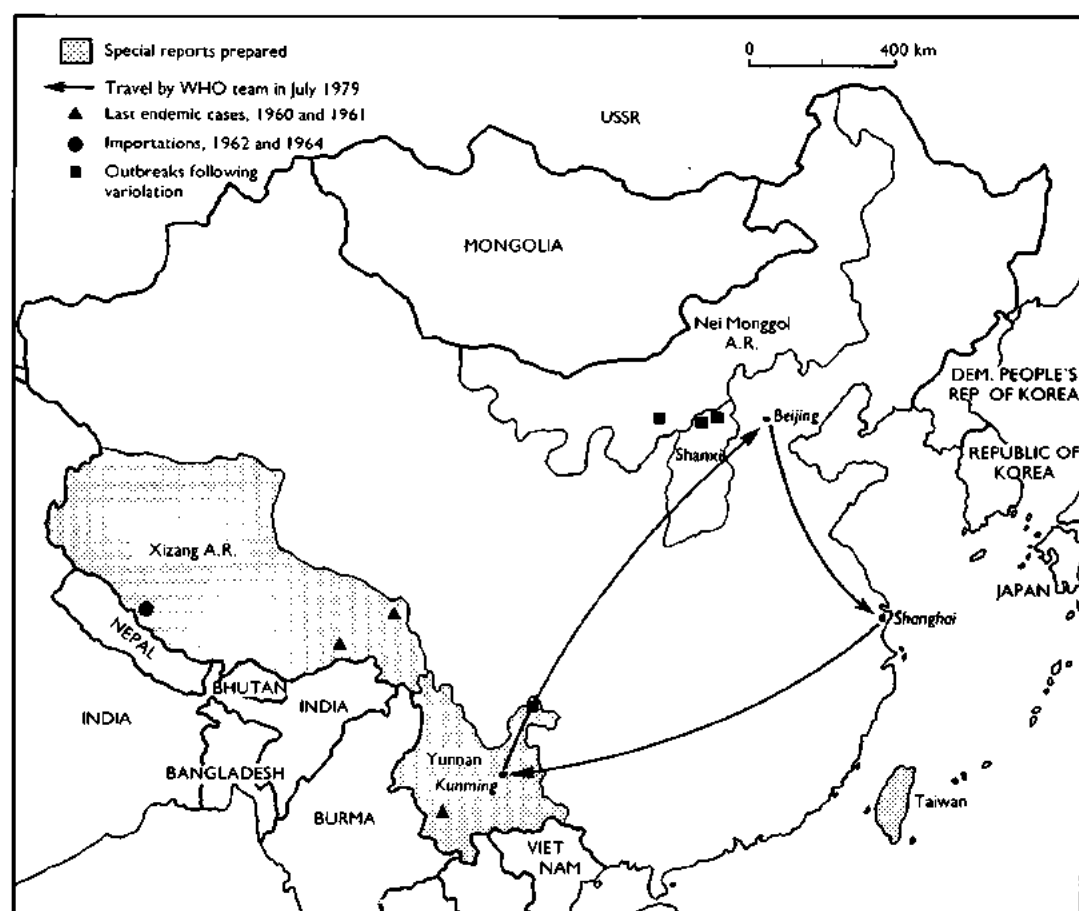

Fig. 27.15. China and neighbouring countries, in relation to certification activities, showing travel by the WHO team in July 1979 and the areas for which special reports were prepared (Provinces of Yunnan and Taiwan; Xizang Autonomous Region [Tibet]). Places where the last cases of endemic smallpox were reported in Xizang in 1960 and in Yunnan in 1961, the site of imported cases in Xizang in 1962 and 1964, and the locations of outbreaks following variolation in northern Yunnan in 1958 and in Nei Monggol Autonomous Region and Shanxi Province in 1962–1965 are also shown.

<sup>c</sup> Importations from Nepal.

WHO/SE/79.151; SME/79.10; SME/79.11, Fenner & Breman). Subsequently, Xu & Jiang (1981) described the elimination of smallpox from Shanghai, and Jiang Yutu published an account of smallpox in China in a Chinese medical encyclopaedia (Jiang, 1985). The description of the eradication of smallpox in China given in Chapter 8 is based on the relevant information in these reports. Three matters of particular importance for the certification programme are described below: smallpox in Yunnan Province and in Xizang Autonomous Region (Tibet), and the location of laboratory stocks of variola virus. Also included in the present chapter is an account of outbreaks of smallpox in northern China in 1962–1965, which did not come to the attention of WHO until the 1980s. The data are shown in Table 27.6.

### Smallpox in Yunnan Province

Yunnan, with a population of about 30 million, is situated in south-western China

and borders on Burma, the Lao People's Democratic Republic and Viet Nam (Fig. 27.16). Although the reported incidence of smallpox had been reduced to zero throughout most of China by the late 1950s (see Chapter 8, Table 8.13), cases continued to occur in Yunnan until 1961 (Table 27.7). Scattered cases were reported from counties in many parts of Yunnan up to 1959, but after that year 5 out of the 6 outbreaks reported occurred in counties adjacent to Burma (Fig. 27.16). The villages in these counties were inhabited by ethnic minorities having strong ties with Burma and there was frequent communication with villages across the border. At the time, communications between these areas and Kunming, the provincial capital, were very poor, and elements of the Kuomintang, by preventing adequate vaccination coverage, had increased the difficulty of eliminating smallpox. Up to 1960, smallpox outbreaks repeatedly occurred on the Burmese side of the border and the disease then passed over into China as the inhabitants carried it across. For example, in 73 of the 461

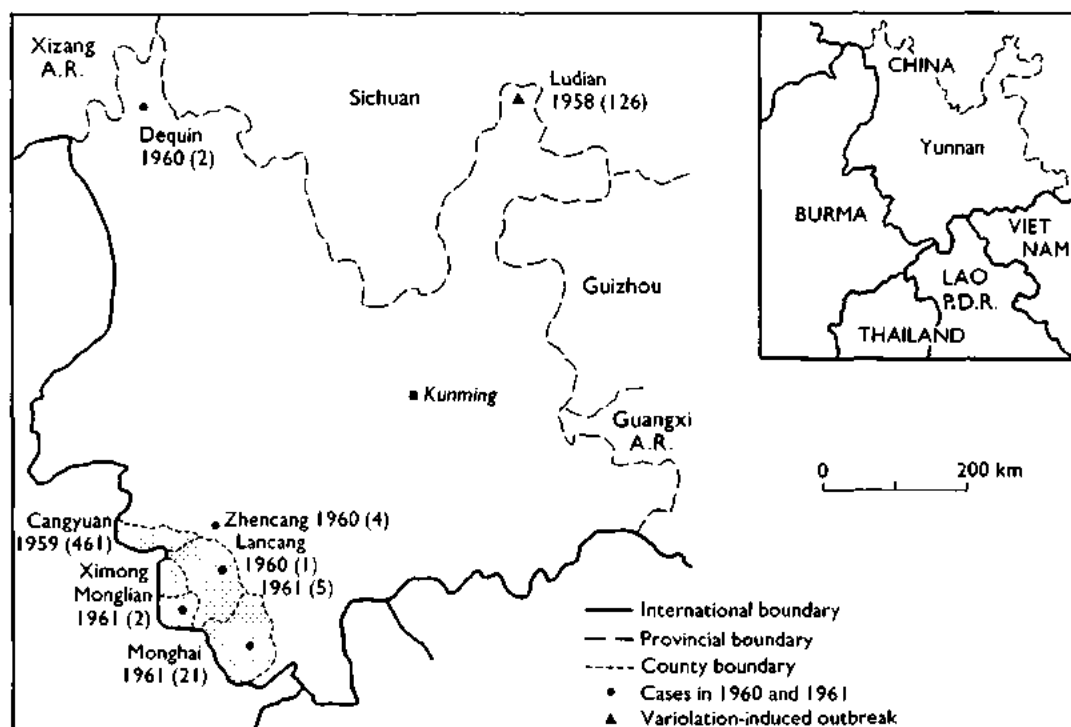

Fig. 27.16. Yunnan Province, showing sites of smallpox outbreaks in 1960–1961 and counties near the Burmese border where vaccination scar and facial pockmark surveys were conducted in 1979. An outbreak of 461 cases occurred in Cangyuan county in 1959 and a variolation-induced outbreak of 126 cases occurred in Ludian county in northern Yunnan in 1958. Numbers next to locations indicate the year in which the number of cases (in parentheses) occurred.

cases (16%) reported in 1959 from Cangyuan county, the disease had been contracted in Burma. It was estimated that at this time between 30% and 60% of the villagers on the Chinese side of the border were vaccinated. After a delayed but intensive vaccination campaign in Cangyuan and neighbouring counties in 1959, which was said to have reached 98.8% of the population, the outbreaks subsided. Seven cases were reported from 3 counties in 1960 and 28 cases in 1961, 5 from Lancang county, 21 from Monghai county, and finally 2 from Monglian county—the last endemic cases in China.

In the border districts in which the last smallpox outbreaks had occurred, vaccination scar and pockmark surveys were conducted in March–May 1979, in preparation for the visit to Kunming by the WHO team. The overall

vaccination rate among 44 771 persons examined in the rural districts was 90.4%, compared with 94.0% for Kunming municipality (Table 27.8). In both areas, the rate was also satisfactory for the age group 0–4 years. The overall frequency of pockmarks in persons in these districts was 6.0%, compared with 0.3% in Kunming municipality (Table 27.9), but the age distribution (Table 27.10) revealed that in Monglian county, in which, as has already been mentioned, the last reported cases occurred in 1961, no person under 22 years of age had facial pockmarks, nor were any pockmarked persons under 20 found elsewhere in Yunnan.

The evidence provided to the Global Commission showed that endemic smallpox had persisted in these remote border areas of Yunnan for several years after it had been eliminated from the rest of China (except Xizang Autonomous Region; see below). However, the pockmark and vaccination scar surveys conducted in 1979 in the counties in which smallpox was last endemic provided reassurance that transmission had been interrupted in the early 1960s and that no further outbreaks had occurred.

### Smallpox in Xizang Autonomous Region (Tibet)

Xizang Autonomous Region (Fig. 27.17) is separated from the neighbouring countries of Bhutan, India and Nepal by the Himalayan mountain chain. Its 1.8 million inhabitants are spread over 1.2 million square kilometres, giving a population density of only 1.5 per square kilometre. Xizang therefore appears to have been a rather unfavourable place for maintaining smallpox transmission, although

<sup>a</sup> None of whom had had smallpox after 1960; ..=data not recorded.

it was periodically subject to epidemics of great severity. In all, 23 cases were reported in 1955 and 4 in 1956, followed by 16 in 1960. This led to a request from the WHO team for a special report, which was forwarded to WHO in November 1979. No further details of the cases in 1960 were available except that 5 of them occurred in Changdu subregion and 11 in Lhasa subregion.

The special report provided details of subsequent vaccination coverage, information on suspected cases of smallpox, and the results of vaccination scar and facial pockmark surveys conducted in August 1979. Between 1960 and 1979, 39 cases of suspected smallpox were investigated in the 3 years 1963, 1965 and 1970. All turned out to be cases of chickenpox. At the time of the Global Commission meeting, the Chinese authorities reported rumours of 4 importations from Nepal into Xizang in the early 1960s, with 1 secondary case. Subsequently Dr Jiang Yutu (personal communications, 1984, 1985) confirmed that, following importations from Nepal, 1 case had occurred in Nielamu county

(Rikeze subregion) in 1962 and 5 cases in 1964.

In addition to routine vaccination, for which freeze-dried vaccine was used from 1965 onwards, mass vaccination campaigns were carried out in 1964 and 1975 to increase the immunity level of the population in areas bordering on India and Nepal. Limited data showed that the take rate in persons undergoing primary vaccination varied between 86% and 95%.

The vaccination scar and facial pockmark surveys in August 1979 covered 15 661 persons in Shannan and Rikeze subregions and Lhasa City (Table 27.11). Vaccination rates were high (91%) among those over 4 years of age but only 57.5% in those below that age. No persons with facial pockmarks were found in Shannan subregion but about 1% of over 12 000 persons examined in Lhasa City and Rikeze subregion, all of them over the age of 20 years, were pockmarked. This evidence reinforced the data from the pockmark survey on Tibetan refugees provided to WHO earlier.

### Province of Taiwan

In 1972, WHO decided to follow the United Nations in recognizing the Beijing government as representing China, considering Taiwan as one of its provinces and referring to the island as "China (Province of Taiwan)".

Unlike mainland China, Taiwan had been an active member of WHO from 1948, when the Organization was established, until 1972, when it was excluded following the above-mentioned decision. In 1978, Taiwan had a population of 17.9 million (7.5 million in 1950) and a comprehensive health services infrastructure. The last big epidemic of smallpox had occurred in 1946-1947: 6754 cases with 2040 deaths. Mass vaccination campaigns with the annual primary vaccination of infants and vaccination of the entire population eliminated endemic smallpox in 1954, after which no cases had been found. The country report, endorsed by the Director-General of Health Services, together with a signed "Declaration of Smallpox-free Status", was judged to be satisfactory by the Global Commission on 8 December 1978, but for purposes of formal certification Taiwan could, of course, only be considered together with China as a whole.

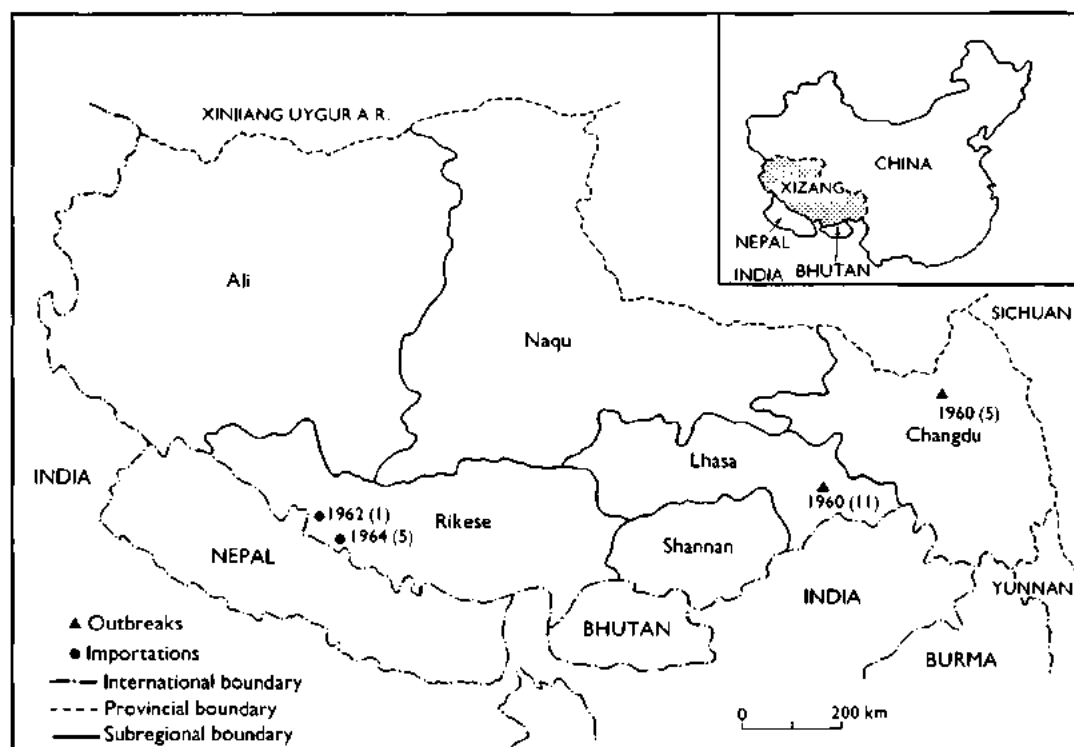

Fig. 27.17. Xizang Autonomous Region (Tibet), showing subregional, provincial and international boundaries, and the sites where the last endemic cases occurred in 1960: 5 cases in Changdu county (Changdu subregion) and 11 cases in Linzhi county (Lhasa subregion). There was 1 case in 1962 and 5 cases in 1964 in Nielamu county (Rikese subregion), associated with importations from Nepal. Numbers next to locations indicate the year in which the number of cases (in parentheses) occurred.

### Variolation in China after 1950

Variolation, initially by insufflation and later by scarification, had been practised in China since about the 10th century (see Chapter 6), and was practised almost as widely as vaccination during the early years of the 20th century. It continued to be used for over a decade after the Liberation in remote rural areas that were at the time served almost exclusively by practitioners of traditional medicine. The Global Commission was told of an outbreak of 126 cases in 1958 in Ludian

county in the north-east corner of Yunnan Province (see Fig. 27.16) which followed variolation by nasal insufflation, 5 years after the last case of endemic smallpox in that county but only a year after the last outbreaks in other counties in northern Yunnan.

Some years after the last meeting of the Global Commission, information was provided by Dr Jiang Yutu (1985; and personal communications, 1984, 1987) about other variolation-induced outbreaks in northern China in the mid-1960s (Fig. 27.18), in Nei Monggol Autonomous Region (1 case in

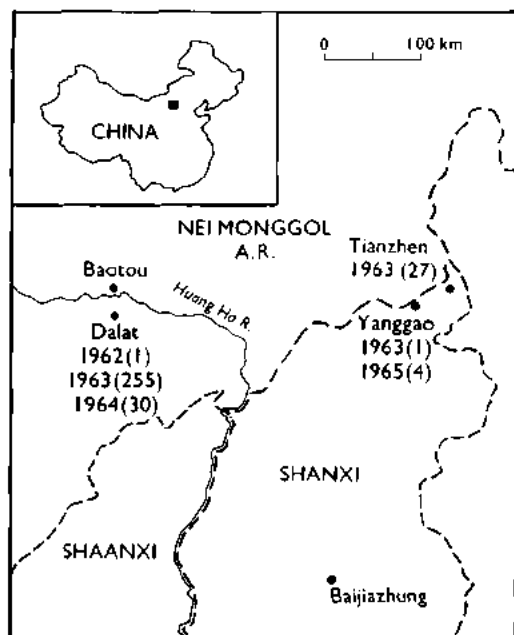

Fig. 27.18. Sites of the outbreaks in northern China, 1962–1965, following variolation. Figures beneath place names indicate the year of the outbreak and the number of cases (in parentheses). (From Jiang Yutu, 1985; and personal communications, 1984, 1987.)

1962, 255 cases in 1963 and 30 cases in 1964) and 2 nearby counties of Shanxi Province (28 cases in 1963 and 4 in 1965).

These incidents have been explained by Dr Jiang Yutu (personal communications, 1984, 1987) as follows. Throughout the whole of continental China between 1959 and 1962, almost everything, including smallpox vaccine, was in short supply. In 1963, just after the country had recovered from this situation, people demanded that their children should be vaccinated but supplies of potent vaccine were not sufficient to ensure the coverage of all areas, especially the mountainous and remote ones. In Nei Monggol and Shanxi, as a result, the inhabitants turned to their local traditional doctors, some of whom had been variolators, maintaining virus in sealed jars containing honey. After smallpox had disappeared from their region in the 1950s (see Chapter 8, Table 8.13), they had continued to maintain the viability of the virus by the annual inoculation of their own children. Thus, when supplies of vaccine failed in the early 1960s, these variolators still had active variola virus, and with the cessation of vaccination many more children became susceptible and many

more were inoculated with the virus. The outbreaks which then occurred were investigated by Dr Zhao Kai, of the National Vaccine and Serum Institute, Beijing, who recovered variola virus both from cases and from the variolation material. Stringent measures were taken to eliminate the practice and supplies of potent freeze-dried vaccine were provided to remove any need for recourse to variolation. As has been pointed out earlier, a massive reorganization of the health services in China in 1965 greatly improved the quality of health care in the rural areas. No cases of smallpox occurred after 1965, either in these areas or elsewhere in China.

### Variola Virus Stocks

Inquiries made by the Chinese Ministry of Health in 1961–1962, 1966 and again in 1978 established that the only variola virus stocks held in laboratories were located in the National Institute for the Control of Biological Products in Beijing. The virus had last been used in 1967, as a positive control during laboratory investigations of material from a suspected case of smallpox. The WHO team noted:

“The laboratory does not conform to WHO standards for facilities storing variola virus. As a depository only, the physical and administrative arrangements seem adequate for the particular situation, but the building housing the virus stocks, and the cabinet itself, would not offer maximum security against a determined saboteur.”

In January 1981 these stocks were destroyed by the Chinese government.

### Review by the Global Commission

WHO's efforts to collect additional information on smallpox in China had eventually resulted in a visit of a team of experts to the country in July 1979 and the accumulation of substantial data that lent support to the view that smallpox had been eradicated. However, there was little time left for review and assessment of these data by the Global Commission, since the target date for global certification was the end of 1979. On 21 August 1979, Arita wrote to members of the Global Commission and submitted to them all the data then available: the country report by the Ministry of Health (WHO/SE/79.142

Rev. 1); a provincial report by the Health Department of Yunnan Province, in which the last endemic case had occurred (SME/79.10); a report on the visit to China by Fenner and Breman (SME/79.11); and a report on smallpox eradication in Taiwan Province. Information on Xizang (Tibet) and vaccine production arrangements did not become available to WHO until November 1979. In the letter, Arita noted that the WHO team believed, from the evidence that it had been able to collect on its visit, that smallpox had been eliminated from China, and specifically requested an answer to the following 3 questions:

(1) Do you think that the Global Commission should now approve certification of smallpox eradication in China?; or

(2) Do you as an individual member of the Global Commission approve certification of smallpox eradication in China, but feel that its final eradication should not be declared until all the Commission members meet again from 6 to 9 December 1979?; or

(3) Do you have any other comments or recommendations which do not fall into the above two categories?

The response of the members of the Global Commission was equivocal; 8 advocated immediate certification, 5 wished to discuss it at the December meeting, and 6 did not reply. Dr Holger Lundbeck, a Commission member from Sweden, expressed a widely held view by saying that, while he had no doubt that smallpox transmission had been interrupted long ago in China, in order to convince the world community, more information should be sought about Xizang for "there will always be people who doubt that eradication has been achieved, in particular in countries as big as China".

Consideration of the certification of smallpox eradication in China was therefore deferred until the meeting of the Global Commission in Geneva in December 1979, which was attended by Dr Zhang Yi-hao from China as a member and Dr Jiang Yutu as an adviser. In addition to the reports previously circulated, 2 further reports were then available: (1) *Supplementary Report about the Eradication of Smallpox in China*, sent to WHO on 17 November 1979 by the Minister of Public Health, Dr Qian Xinzong, which provided information on the production of smallpox vaccine, the health service structure, and the quarantine services; and (2) a report

(WHO/SE/79/151) which included details of vaccination campaigns and coverage in Xizang, the last outbreaks there, and the results of a pockmark survey carried out in August 1979, which has already been described. Having considered all the data and heard reports from Dr Zhang Yi-hao and Dr Jiang Yutu, the Commission certified China to be free of smallpox on 9 December 1979.

## CONCLUSIONS

In every health programme, success depends not only on the scientific technology but also on the managerial arrangements and political negotiations which pave the way for its implementation. The certification activities in the Horn of Africa and China illustrate how scientific technology and managerial and political arrangements were developed in parallel in order to accomplish a single task.

With the certification of the Horn of Africa and China, the chapter on the certification of the global eradication of smallpox, which had commenced in 1971 when Brazil recorded the last case on the South American continent, was closed. Activities had been greatly intensified since 1976 when it became apparent that global eradication was imminent. Four years of effort, from 1976 to 1979, had been successful in confirming that the world had become free of smallpox. This was the first time in history that human efforts had succeeded in eliminating a disease—and one which had been feared for thousands of years. Neither the vigorous operational campaign for the eradication of the disease nor the diligent certification programme was free from technical and human errors. Nevertheless, both were eventually successful.

The Global Commission met in Geneva from 6 to 9 December 1979. It had before it a draft final report which had already been reviewed and revised by 12 members of the Commission in Nairobi in October. The meeting concentrated its attention on the conclusions and recommendations (World Health Organization, 1980). After 4 days of intensive discussions, it accepted the following conclusions:

(1) Smallpox eradication had been achieved throughout the world.

(2) There was no evidence that smallpox would return as an endemic disease.

L. B. ANCO

**Plate 27.10.** Members of the Global Commission for the Certification of Smallpox Eradication, 9 December 1979. From left to right, front row: S.S. Marennikova (USSR), J. Azurin (Philippines), P.N. Burgasov (USSR), F. Fenner (Australia; Chairman), J. Kostrzewski (Poland; Vice-Chairman), D.A. Henderson (USA), W. Koinange (Kenya), Zhang Yihao (China); back row: P.F. Wehrle (USA; Rapporteur), R.N. Basu (India), J.M. Aashi (Saudi Arabia), H.B. Lundbeck (Sweden), B.A. Rodrigues (Brazil), K.R. Dumbell (United Kingdom), R. Netter (France), I. Tagaya (Japan), J.S. Moeti (Botswana), Kalisa Ruti (Zaire), P.N. Shrestha (Nepal), A. Deria (Somalia).

The 19 recommendations covered all aspects of operations relevant to orthopox-viruses and the diseases that they cause in a world from which smallpox had been eradicated. The meeting closed on 9 December 1979 with a ceremony in which the members of the Global Commission signed a parchment declaring that the world was free of smallpox (see frontispiece).

The final report of the Global Commission, *The Global Eradication of Smallpox* (World Health Organization, 1980), was published in the 6 official languages of the World Health Organization and its conclusions and recommendations were accepted without change by the Thirty-third World Health Assembly on 8 May 1980.

## INTRODUCTION

In order to convince the world community that smallpox had indeed been eradicated globally, WHO developed a comprehensive and sophisticated system for the certification of smallpox eradication, culminating in the final meeting in December 1979 of the Global Commission for the Certification of Smallpox Eradication (see Chapter 24). The Global Commission foresaw that the certification of eradication was not enough in itself—steps would have to be taken over the ensuing years to maintain public confidence in the reality of eradication and to ensure that advantage was rapidly taken of the benefits of the achievement, such as the ending of vaccination against smallpox. With this aim in view, the Commission's final report (World Health Organization, 1980) listed 19 recommendations indicating the activities to be undertaken during the years following the declaration by the Thirty-third World Health Assembly on 8 May 1980 that smallpox had been eradicated throughout the world.

The 19 recommendations made by the Global Commission were unanimously endorsed by the World Health Assembly on the same date (resolution WHA33.4). They dealt with post-eradication policies under 8 headings: (1) smallpox vaccination policy; (2) reserve stocks of vaccine; (3) investigation of suspected cases of smallpox; (4) laboratories retaining variola virus stocks; (5) human monkeypox; (6) laboratory investigations; (7) documentation of the smallpox eradication programme; and (8) WHO Headquarters staff.

Concurrently with the declaration of the global eradication of smallpox the Global Commission was dissolved, and in 1981 a new 6-member committee—the Committee on Orthopoxvirus Infections—was established by the Director-General of WHO. Its membership was drawn from the Global Commission, whose chairman, Fenner, also became chairman of the Committee. Except in 1985, this Committee met annually in Geneva from 1981 to 1986, critically reviewed the progress made in the post-smallpox-eradication programme and advised WHO on the implementation of the Global Commission's recommendations. The Committee was serviced and the implementation of post-eradication activities supervised by the Smallpox Eradication unit, which continued to exist, though with a reduced staff (consisting of 3, later 2, medical

officers, an operations officer and support staff), all of whom had had extensive experience in the eradication programme. In the regional offices, all activities related to the post-eradication programme were transferred to the general programme of disease control and prevention or to the Expanded Programme on Immunization.

In this chapter, the post-eradication programme activities carried out between 1980 and 1986 are described, each of the 8 groups of recommendations being considered in turn. Each section is preceded by the relevant statement from the final report of the Global Commission (World Health Organization, 1980) together with the corresponding recommendations.

## VACCINATION POLICY

*"Smallpox vaccination of the general public. As smallpox has been eradicated, smallpox vaccination is no longer justified. Because vaccination may result in serious complications, which are occasionally fatal, no one except investigators at special risk should be vaccinated in any country including those where monkeypox cases have occurred.*

*"Recommendation (1). Smallpox vaccination should be discontinued in every country except for investigators at special risk.*

*"Smallpox vaccination certificates for international travellers. With the certification of global eradication of smallpox, no country should now require vaccination certificates from international travellers.*

*"Recommendation (2). International certificates of vaccination against smallpox should no longer be required of any travellers."*

## Routine Vaccination Programmes

In North America and in many countries of Europe and the Western Pacific Region, routine vaccination programmes had ceased before recommendation (1) was made (Table 28.1).

The health administrations of countries in other regions, however, weighed the risks and benefits of smallpox vaccination in the light of the progress made with the global smallpox eradication programme. In previously endemic countries, international commissions for the certification of smallpox eradication had recommended that vaccination programmes

<sup>a</sup> The figures are those for the end of each of the years in question.<sup>b</sup> Based on the membership of WHO of the countries in the different WHO regions as at January 1984.

should be maintained until global eradication had been certified. When this occurred, in May 1980, these programmes were soon curtailed or discontinued, particularly in countries that depended on WHO for their supplies of vaccine. Of the 156 Member States of WHO at that time, 52 were still conducting routine smallpox vaccination programmes at the end of 1980, but by the end of 1983 this number had been reduced to 2—namely, Albania, in which both primary vaccination and revaccination continued to be performed, and France, in which only revaccination was recommended. Both these countries stopped all routine vaccination in 1984.

The official discontinuation of routine vaccination programmes, however, did not always mean that vaccination had ceased altogether. In many countries, both developed and developing, appropriate instructions were not always effectively promulgated by the central health administration, and local vaccination programmes sometimes continued to be conducted. The distribution of vaccine could be readily controlled in countries in which production was carried out in national laboratories, but such control was more difficult in those in which private companies produced vaccine and sold it on request. In the USA, a few cases of severe complications (e.g. eczema vaccinatum and progressive vaccinia) occurred when vaccinia virus was used for the treatment of herpes simplex, a form of therapy with a long history but one whose effectiveness was open to question. Eventually, agreement was reached in the USA in 1984 that, apart from making provision for the armed services, the producer would restrict the supply of smallpox vaccine to the Centers for Disease Control, for use by

laboratory workers where indicated. By means of announcements in the *Weekly epidemiological record* and communications with governments, WHO intervened several times to advise that vaccination programmes should be stopped, stressing the risk of complications. In addition, in 1983, the Smallpox Eradication unit contacted all vaccine producers to urge that no vaccine should be made available for civilian use.

Although routine vaccination of the general public was speedily abandoned in most countries, military personnel continued to be vaccinated. As a result, incidents occurred in several countries in which a newly vaccinated recruit infected a close contact, often in the home (Laboratory Centre for Disease Control, 1981; *Morbidity and mortality weekly report*, 1984; *Journal of the American Medical Association*, 1985). Although on scientific grounds the vaccination of military personnel could have been discontinued at the same time as that of the civilian population, decisions whether or not to do so were based on political considerations, and WHO could do little to influence them. However, as time went on, an increasing number of countries discontinued the vaccination of military personnel. In order to prevent accidental vaccinia infections of civilians, the WHO Committee on Orthopoxvirus Infections recommended in 1984 that "military personnel who have been vaccinated be confined to their bases and prevented from contacting unvaccinated persons for a period of two weeks following vaccination" (WHO/SE/84.162). This recommendation was made known to all Member States. Reviewing the situation in March 1986, the Committee on Orthopoxvirus Infections rec-

ommended that "smallpox vaccination to protect military personnel against the disease be terminated" (*Wkly epidem. Rec.*, 1986b).

Recommendation (1) exempts only "investigators at special risk" from the recommendation that vaccination should be discontinued. This group includes the following 3 categories: (1) Investigators who handle variola or monkeypox virus in a laboratory—a very small group. Everyone who enters such laboratories should undergo regular annual or triennial vaccination. (2) Investigators who work with other orthopoxviruses that are infectious for man (vaccinia and cowpox viruses). Triennial vaccination of those who handle such viruses is recommended. (3) Special surveillance teams investigating cases of human monkeypox in Zaire. At the present time, vaccination of the general population in areas in which human monkeypox virus is present is not recommended, on the grounds that the risk of monkeypox infection does not warrant either the cost of vaccination or its risks. In all, the number of persons for whom smallpox vaccination is still recommended is

very small, amounting to only a few hundred persons throughout the world.

### Vaccination Certificates for International Travel

At the beginning of 1980, 23 of the 155 countries for which information was available still required international travellers to hold an international certificate of vaccination against smallpox. In May 1981 the Thirty-fourth World Health Assembly formally struck smallpox from the International Health Regulations and in 1983 the new edition of the International Certificates of Vaccination no longer contained any pages for smallpox vaccination (Plate 28.1).

After the declaration of the global eradication of the disease, the number of countries officially requiring international travellers to hold a certificate of vaccination against smallpox quickly decreased to only 2 (Chad and Democratic Kampuchea) in 1981 and to none in 1982. These figures are based on the reports

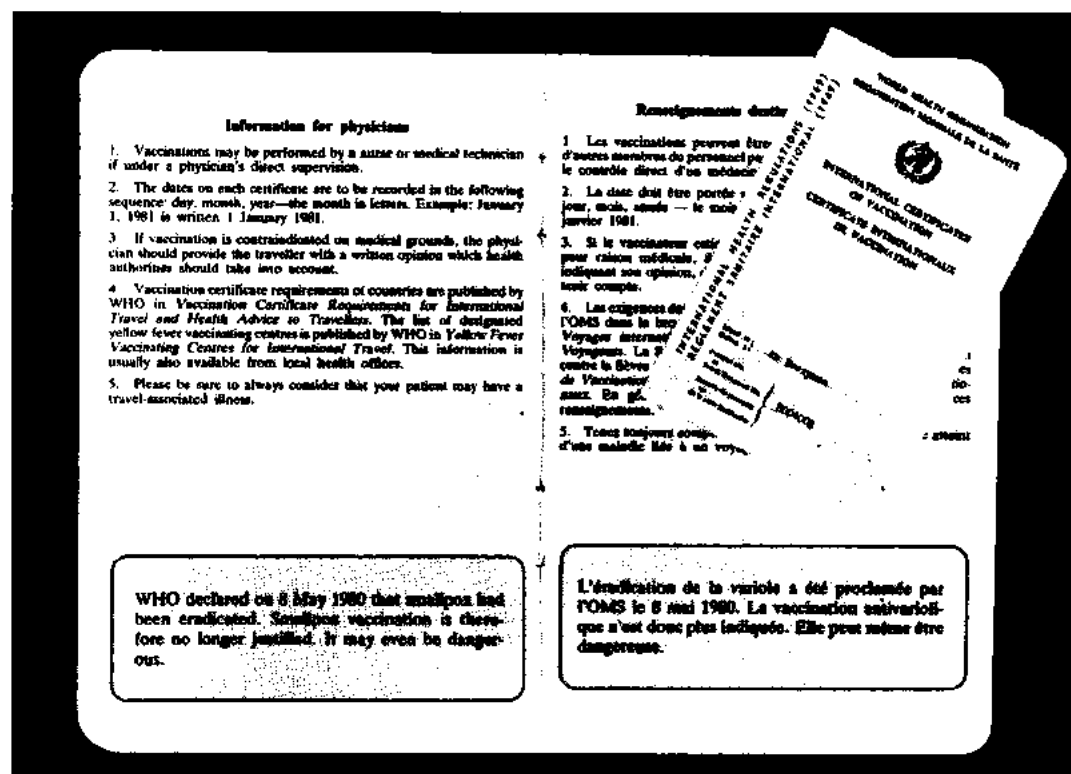

Plate 28.1. The 1983 version of the International Certificate of Vaccination. It no longer contains any pages for smallpox vaccination but includes a statement that it is no longer justified.

to WHO of national health administrations, but in fact during the first few years of the 1980s international travellers were sometimes asked for certificates of smallpox vaccination by health officers at ports or airports or by consulates when they applied for visas, or were informed that they would need certificates by those through whom they arranged their travel. This occurred in developed as well as developing countries, both because of poor communications between the ministries of health and other national authorities, such as ministries of foreign affairs and their representatives abroad, and because of the difficulty of ensuring that travel agencies were properly informed and gave correct advice to their clients. Following repeated interventions by WHO, the number of such incidents gradually diminished and by 1984 only a few occurred.

### RESERVE STOCKS OF VACCINE

"Although human-to-human transmission of smallpox has been interrupted everywhere and the Global Commission believes that the likelihood of reintroduction of smallpox from laboratories or natural or animal reservoirs is negligible, it is prudent for WHO and national health authorities to be prepared for unforeseen circumstances. One measure that should be taken is to ensure that adequate reserves of potent freeze-dried vaccine are available. This vaccine should be stored at  $-20^{\circ}\text{C}$  and its potency periodically checked. Seed lots of vaccinia virus for the future preparation of vaccine should be maintained, and stocks of bifurcated needles should be available.

"*Recommendation (3).* Sufficient freeze-dried smallpox vaccine to vaccinate 200 million

people should be maintained by WHO in refrigerated depots in two countries, together with stocks of bifurcated needles.

"*Recommendation (4).* The stored vaccine should be periodically tested for potency.

"*Recommendation (5).* Seed lots of vaccinia virus suitable for the preparation of smallpox vaccine should be maintained in designated WHO collaborating centres.

"*Recommendation (6).* National health authorities that have vaccine stocks should be asked to inform WHO of the amount of vaccine maintained."

### WHO Reserve Stocks of Vaccine

In December 1980, the Smallpox Eradication unit drew up detailed procedures for implementing recommendations (3) and (4); these were set out in a document entitled *Management of reserve stocks of vaccine in the post-smallpox eradication era* (WHO/SE/80.158 Rev.1), which was approved by the WHO Committee on Orthopoxvirus Infections in March 1981. The recommended storage temperature of  $-20^{\circ}\text{C}$  or lower was based on previous experience in the potency testing of batches of vaccine produced in the Connaught Laboratories, Canada; the Lister Institute, United Kingdom; the National Institute of Public Health, Netherlands; the Swiss Serum Institute, Switzerland; and Wyeth Laboratories, USA (Table 28.2). These batches had been stored at temperatures ranging from  $+4^{\circ}\text{C}$  to  $-20^{\circ}\text{C}$  over a period of 8–13 years. The potency of the great majority had remained at an adequate level, and it was

Table 28.2. Smallpox vaccine titres<sup>a</sup> after long-term storage: typical results from laboratories in 4 countries

Country and batch number	Year of manufacture	Original titre <sup>b</sup>	Storage temperature	Storage period (years)	Titre on retesting
Canada: 1517-12	1971	..	$4^{\circ}\text{C}$	8	0.1
Switzerland: L4695	1966	8.0	$-20^{\circ}\text{C}$	10	8.0
United Kingdom: 701	1963	8.0	$-15^{\circ}\text{C}$	13	7.9
USA: 177501	1963	..	$5^{\circ}\text{C}$ for 7 years; $-20^{\circ}\text{C}$ for 4 years	11	0.2

<sup>a</sup> Expressed as  $\log_{10}$  pock-forming units per ml of reconstituted vaccine.

<sup>b</sup> .. = data not available.

assumed that storage at a temperature of  $-20^{\circ}\text{C}$  would suffice to maintain a satisfactory titre for many years.

At the end of 1980, 68 million doses of vaccine were stored in Geneva and 6 million doses in New Delhi. These stocks had been donated by 9 countries—Belgium, Canada, the German Democratic Republic, India, the Islamic Republic of Iran, the Netherlands, Sweden, the USSR and the USA—India and the USSR being the major donors. Between 1981 and 1985, further donations were made by Belgium, India and the USSR, but some stocks were destroyed (see below), so that the total reserve stocks at the end of 1985 amounted to 5 034 178 vials, in 459 batches. If bifurcated needles were to be used, this amount of vaccine would be sufficient to vaccinate some 300 million persons. About 3.7 million bifurcated needles are also stored in Geneva.

These stocks can be made available for any country needing to undertake emergency containment measures, but only if a presumptive diagnosis of smallpox has been confirmed by expert clinical and laboratory investigations (see below).

### *Testing*

Batches of vaccine will continue to be sampled periodically for as long as the WHO reserve is maintained, in accordance with the procedure laid down in document WHO/SE/80.158 Rev. 1; in this way the potency of all batches can be regularly monitored so that any decline in potency can be detected without delay.

Testing is carried out by the National Institute of Public Health, Bilthoven, Netherlands, which remains the WHO International Collaborating Centre for Smallpox Vaccine. In order to ensure that the data are comparable with those obtained in previous years, the Institute has decided to continue potency testing by pock counting on the chorioallantoic membrane, rather than by the newer and somewhat more accurate technique of plaque assay.

### *Problems encountered*

The problems encountered during the implementation of the recommendations regarding reserve stocks are described below.

*Location.* In accordance with recommendation (3), two depots were established in 1981,

one at the Société des Gares Frigorifiques et Ports Francs de Genève, Switzerland, and the other in the WHO Regional Office for South-East Asia, New Delhi, India. In the Geneva depot the requisite temperatures were satisfactorily maintained, but in the New Delhi depot the temperatures fluctuated from  $-10^{\circ}\text{C}$  to  $+10^{\circ}\text{C}$ . In 1982, the Smallpox Eradication unit arranged for a refrigeration consultant to visit the Regional Office depot in New Delhi, but it still proved impossible to keep the temperature at the proper level. In addition, the depot was flooded during heavy rains, and all the ampoules of diluent, which were stored separately from the vaccine, were submerged and had to be destroyed. In February 1984 the entire stock of vaccine in the New Delhi depot was transferred to Geneva. It was expected that, because of the high heat stability of freeze-dried smallpox vaccine, the stock would not have been affected by the temperature fluctuations, and, indeed, satisfactory results were obtained when all the batches were tested before their transfer.

The Global Commission's recommendation that vaccine depots should be located in two countries could thus not be implemented. After the difficulties in New Delhi, attempts were made to find a second depot in Japan or the USA, but these failed because the veterinary health authorities of these countries objected to the introduction of calf skin vaccine, which might contain foot-and-mouth disease virus. The Committee on Orthopoxvirus Infections therefore agreed to divide the vaccine stocks equally between the cities of Geneva and Lausanne, which are about 60 kilometres apart and connected by a motorway. Geneva has good communications with the rest of the world, and experience during the smallpox eradication programme showed that, in the event of an emergency, vaccine could be dispatched to any country in the world within 24 hours.

*Potency.* Although there was good evidence that vaccine could be stored indefinitely at  $-20^{\circ}\text{C}$ , tests carried out in Bilthoven between 1981 and 1983 revealed that the potency of 6 batches of vaccine, from the Islamic Republic of Iran (200 000 doses of vaccine for multiple puncture), and the USA (1.9 million doses of jet injector vaccine), had declined. No attempt was made to determine the causes of this decline; the most probable explanation was that the ampoules were not

WHO / M. VANAPPELGHEN, 1984

**Plate 28.2.** The reserve of smallpox vaccine in Geneva being checked by J.F. Wickett. At  $-20^{\circ}\text{C}$  it may be expected to retain its potency for many years. Nevertheless, samples are periodically tested, in accordance with a statistically designed procedure.

properly sealed or that the vaccine had too high a moisture content. These batches were removed from the stock and destroyed. Otherwise all samples tested have been found to be of satisfactory potency (Table 28.3).

In 1984, the Committee on Orthopoxvirus Infections discussed the need to keep about 7 million doses of jet injector vaccine donated by Canada, Sweden and the USA. In the Committee's view, bifurcated needles, because of their simplicity, were much to be preferred to jet injectors for the administration of smallpox vaccine should any emergency arise, so that the cost of keeping the jet injector vaccine was not justified. The donor countries were asked whether they would like the batches to be returned to them, but since none was willing to take them, they were destroyed.

#### *Long-term maintenance*

During the period 1981–1985 the existence of the WHO vaccine reserve made it much easier for Member States to decide to discontinue both smallpox vaccination and vaccine production. The annual cost of maintaining the vaccine depots amounted to US\$21 000 and that of testing to US\$3000. Reviewing the situation in March 1986, the Committee on Orthopoxvirus Infections concluded that

**Table 28.3.** Smallpox vaccine reserve stocks: typical results of initial and subsequent tests of batches provided by manufacturers in 7 countries, 1978–1983<sup>a</sup>

<sup>a</sup> Tested by the WHO International Collaborating Centre for Smallpox Vaccine, Bilthoven, except where indicated; titres expressed as  $\log_{10}$  pock-forming units per ml of reconstituted vaccine. M = year manufactured; R = year received; .. = data not available. Vaccine was stored at  $-4^{\circ}\text{C}$  before 1980, and at  $-20^{\circ}\text{C}$  thereafter.

<sup>b</sup> Result of test carried out by manufacturer.

<sup>c</sup> Stored initially at the WHO Regional Office for South-East Asia, New Delhi, India.

smallpox vaccine reserves were no longer required and recommended that the maintenance of a global reserve by WHO was no longer indicated. However, it suggested that a decision to offer to return vaccine to donor countries should not be implemented until the situation had been considered by an *ad hoc* committee to be convened by WHO (*Wkly epidem. rec.*, 1986b).

### National Stocks of Vaccine

In addition to the WHO reserves, 22 countries reported in 1985 that they had their own national vaccine reserves, which amounted to over 100 million doses, though only about 84 million were properly maintained (Table 28.4). The national health administrations of the countries concerned are responsible for monitoring the potency of these stocks.

### Seed Lots of Vaccinia Virus

Seed lots of vaccinia virus produced and kept by the National Institute of Public Health, Bilthoven (see Chapter 11), have been distributed to 3 WHO collaborating centres—namely, the Centers for Disease Control, Atlanta, the National Health Laboratory, Paris, and the National Institute of Health, Tokyo. In addition, in 1985 13 laboratories in countries in which vaccine production had ceased held seed lot material (see Table 28.5), so that, if necessary, production could be rapidly resumed. If there were ever a national emergency, or if the WHO reserve were short of potent vaccine, the seed

lots stored in the WHO collaborating centres could be made available to any country that needed to produce vaccine.

### Vaccine Production Laboratories

In 1975, towards the end of the Intensified Smallpox Eradication Programme, 84 laboratories were producing freeze-dried or liquid vaccine, the latter being used for routine vaccination programmes in some countries with temperate or cold climates. A few countries discontinued production during the next few years, and, after the declaration of smallpox eradication in 1980, many more did so, often when the national health administrations discontinued routine smallpox vaccination programmes (Table 28.5).

In 1985, only 14 laboratories in 11 countries were still producing vaccine, mainly for the use of national defence forces or to stock national emergency reserves.

### INVESTIGATION OF SUSPECTED SMALLPOX CASES

"Experience in many countries indicates that reports of suspected cases of smallpox can be expected to be received from many sources for several years after the certification of global eradication. The importance of thorough investigation of these reports, if necessary with laboratory testing, is illustrated by the fact that one such report led to the recognition of human monkeypox. It is also important that public confidence in the fact of eradication should be maintained by thorough and prompt investigation of all reports and disclosure of the results to health officials throughout the world.

Table 28.4. Known national stocks of smallpox vaccine, by WHO region, 1985<sup>a</sup>

WHO region	Number of countries	Number of doses <sup>b</sup>	
		Held	Properly maintained <sup>c</sup>

Total	76	73	62	26	22	15	12	11	11	13

<sup>a</sup> Excluding those still producing vaccine.

"Suspected smallpox cases should therefore be investigated by experienced personnel. WHO should provide an effective system to promote, coordinate, and participate in the investigation of suspected smallpox cases. The international smallpox rumour register that was established by WHO in Geneva in January 1978 should be maintained.

"The reward of US\$1000 established by the Director-General in 1978 in accordance with resolution WHA31.54 should be discontinued, since global eradication has now been certified.

"*Recommendation (7).* In order to maintain public confidence in the fact of global eradication, it is important that rumours of suspected smallpox, which can be expected to occur in many countries, should be thoroughly investigated. Information should be provided to WHO, if requested, so that it can be made available to the world community.

"*Recommendation (8).* WHO should maintain an effective system to coordinate and participate in the investigation of suspected smallpox cases throughout the world. The international smallpox rumour register should be maintained."

### Guidelines for the Management of Suspected Cases of Smallpox

Early in 1981, WHO distributed to all national health administrations a document entitled *Management of suspected cases of smallpox in the post-eradication period* (WHO/SE/80.157 Rev. 1), which provides a practical guide on how to act if a report of a suspected case of smallpox is received. One of the most important pieces of advice given is that vaccination should not be carried out unless a presumptive diagnosis of smallpox has been established, based on an examination by a physician with extensive experience in the clinical

diagnosis of the disease and on a laboratory report that poxvirus particles have been demonstrated by electron microscopy. This advice was included because, when the document was being prepared, certain health officials who were not convinced that eradication had been achieved had recommended that vaccination programmes should be undertaken if a suspected case of smallpox were to be reported.

### The International Rumour Register

In accordance with recommendations (7) and (8), post-smallpox-eradication surveillance was initiated by the Smallpox Eradication unit in 1980 and is being continued; 131 rumours reported to WHO between January 1980 and December 1986 were investigated with the results shown in Table 28.6. In fact, only a minority of rumours come to the attention of WHO Headquarters, the majority being dealt with at country level without being referred to WHO. In India, for example, about 2000 rumours were investigated and 79 specimens examined virologically between 1980 and 1984.

The main sources of rumours reaching WHO Headquarters have been the general public, tourists, physicians and the mass media. On receiving information of a rumour, WHO Headquarters usually contacts the WHO regional office concerned and requests that an investigation should be undertaken. If the situation is considered to be urgent, WHO Headquarters contacts the informant direct, asking for more details; at the same time it requests the government health services, as well as WHO epidemiologists in the country

or at the regional office concerned, to investigate the rumour. The results of investigations of rumours deemed to be important because of the wide publicity they have received, or for other reasons, are published promptly in the *Weekly epidemiological record*, so that Member States are kept informed.

All these rumours have turned out to be false alarms, thus confirming that there has been no evidence of smallpox anywhere in the world since the declaration by WHO of smallpox eradication in 1980.

In checking rumours reported to WHO, use is made of the diagnostic services provided by the WHO collaborating centres at the Centers for Disease Control, Atlanta, USA, and the Moscow Research Institute for Viral Preparations, Moscow, USSR. All investigations, both by the WHO collaborating centres and by national laboratories, have failed to reveal variola virus in any sample tested.

#### *Nature and sources of rumours reported*

As was mentioned above, 131 rumours were reported to WHO Headquarters between January 1980 and December 1986 (Table 28.6). About half the total number of these reports were received between 1980 and 1982; by 1985-1986, only 10 were being reported annually. Experience in India, where most rumours were investigated locally without being referred to WHO, was comparable, the yearly totals of specimens investigated by the smallpox reference laboratory of the National Institute of Communicable Diseases being 30, 16, 8, 10 and 15, respectively, over the period 1980-1984.

Of the 131 rumours reported to Headquarters, about 70% were investigated and the

results made known to WHO within 2 months, but delays of up to 6-9 months occurred in some cases. The principal diseases misdiagnosed as smallpox were chickenpox and measles, which had also been the main causes of misdiagnosis before smallpox was eradicated (see Chapter 1). A significant proportion of the rumours arose from inaccurate reporting or recording. Even cholera was sometimes reported as smallpox in the mass media. Human monkeypox was occasionally misdiagnosed as smallpox and reported as such, but these cases have been excluded from the register since they occurred in Zaire, in which the disease has been under special surveillance since 1982 (see below).

#### *Examples of the kinds of rumours reported*

Rumours arose from various sources and a wide variety of actions were taken to investigate them. A few examples are given below; others have been described by Khodakevich & Arita (1985).

*Rumours circulated by the mass media.* The national and international news media were a common source of rumours and occasionally reported outbreaks of smallpox in areas in which epidemics of an infectious disease had occurred and caused several deaths. Expecting to find an increased incidence of infectious diseases in refugee camps and regions affected by famine, reporters sometimes alleged the occurrence of smallpox despite the lack of any supporting evidence. For example, *Newsweek*, on 26 November 1984, carried an article describing the famine situation in Ethiopia, in which it stated: "... Starvation brought other ailments with it, including influenza, measles, tuberculosis, diarrhea, smallpox, ty-

Table 28.6. International rumour register: suspected cases of smallpox reported to WHO Headquarters, Geneva, by WHO region, 1980-1986

WHO region	Number of reports								Results of investigation			
	1980	1981	1982	1983	1984	1985	1986	Total	Chicken-pox	Measles	Skin disease	Erroneous reports by news media
Africa	9	11	5	5	6	5	6	47	18	7	8	14
Americas	3	6	0	4	5	0	1	19	11	1	3	4
South-East Asia	12	4	3	8	8	5	2	42	17	7	2	16
Europe	1	2	0	0	0	0	0	3	3	0	0	0
Eastern Mediterranean	4	3	2	1	2	0	0	12	2	1	2	7
Western Pacific	2	4	0	1	0	0	1	8	3	3	1	1
Total	31	30	10	19	21	10	10	131	54	19	16	42

phus and kwashiorkor...". When WHO drew the attention of the editor of the magazine and of health staff in Ethiopia to the erroneous nature of this report, it transpired that there had been cases of measles, but not of smallpox.

*Rumours related to variolation.* On 18 November 1983, WHO was informed by the Kenyan health services that a suspected case of smallpox had occurred in Kenya in an adult male from Nandi Hill Estate in the Rift Valley Province. The patient was hospitalized on 8 November and died on 15 November, 3 days after developing a papular rash, mainly on the face and limbs. Scab specimens were taken and sent immediately from Nairobi to the WHO collaborating centre at the Centers for Disease Control, Atlanta.

It was noted that the patient, whose vaccination status was not known, had been a traditional healer, perhaps a former variolator who might have inoculated himself with old material still in his possession, but that his 5-year-old son had had chickenpox shortly before the onset of the illness. On 21 December, the collaborating centre in Atlanta informed WHO that herpesvirus particles had been seen in the specimens by electron microscopy, and this information was immediately relayed to the Kenyan health authorities. Virus cultivation on the chorioallantoic membrane gave negative results for smallpox. The prompt reporting and collection of specimens by the Kenyan health services, and the equally prompt laboratory investigation by the WHO collaborating centre, led to the correct diagnosis of this case within a few days of its occurrence.

*Scabs on old corpses.* Early in 1985 some student archaeologists were engaged in excavating the vaults of a church near Spitalfields, London. One coffin was found to contain the well-preserved remains of a person who had died of smallpox in about 1840. As a precaution, the United Kingdom Health and Safety Executive closed the site and vaccinated the 3 student archaeologists concerned, and "scab" material from the corpse was sent to the WHO collaborating centre in Atlanta. Exhaustive electron microscopic examination there revealed one object that might have been a poxvirus particle but all attempts at cultivation were unsuccessful. Later, Fornaciari & Marchetti (1986) published photographs of objects that they considered to be

poxvirus particles on the basis of electron microscopy of material taken from a vesiculopustular eruption on the mummy of a 2-year-old boy who died in Naples in the 16th century. Exhaustive testing in the WHO collaborating centres failed to reveal any infectious virus in samples of this material. Bodies buried in Arctic permafrost, referred to in Chapter 30, might pose a greater risk, although very few smallpox victims would have been interred in such places.

#### *Efficacy of the international rumour register*

The international rumour register constituted the ultimate level of reference in a system operating primarily at the country or WHO regional office level for the investigation of rumours of smallpox, although it often received rumours direct from a source rather than through the network. This continuing surveillance failed to find any evidence of the recurrence of smallpox anywhere in the world. Had there not been such surveillance by WHO, backed up by special investigations at the WHO collaborating centres, it is highly likely that some rumours would have had significant repercussions, resulting in damage to public confidence in the WHO declaration, and even the initiation of a mass vaccination programme against smallpox. In the event, vaccination was never needed nor was it ever recommended, since no case occurred which satisfied the requirements laid down by the guide to the management of suspected cases of smallpox. The confidence thus built up undoubtedly assisted in ensuring the universal discontinuation of routine smallpox vaccination.

### LABORATORIES RETAINING VARIOLA VIRUS STOCKS

"A committee of experts meeting in February 1979 advised the Global Commission that it was necessary for scientific reasons to preserve stocks of variola virus in a few laboratories, but that the position should be reviewed in 1982. In view of the potential danger of reintroduction of smallpox from variola virus stocks held in laboratories, no more than four WHO collaborating centres should be approved as suitable for the storage of and work with variola virus in accordance with WHO safety standards. These WHO collaborating centres should report annually to WHO and their containment facilities should be periodically inspected to ensure that storage is secure and that safe operating conditions are maintained. All other laboratories

should be asked to destroy any stocks of variola virus that they hold, or to transfer them to an approved WHO collaborating centre.

*"Recommendation (9).* No more than four WHO collaborating centres should be approved as suitable to hold and handle stocks of variola virus. A collaborating centre would be approved only if it had adequate containment facilities. Each such centre should report relevant information on its safety measures annually to WHO and be inspected periodically by WHO.

*"Recommendation (10).* Other laboratories should be asked to destroy any stocks of variola virus that they hold, or transfer them to an approved WHO collaborating centre."

### Reduction in Number

As early as 1976 the Smallpox Eradication unit began trying to reduce the number of laboratories holding stocks of variola virus (see Chapter 30). This was successful in that the number of such laboratories fell from 75 in 1975 to 7 at the time of the final meeting of the Global Commission in December 1979 (see Chapter 30, Tables 30.6 and 30.7).

A laboratory-associated outbreak of smallpox in Birmingham, England, in 1978 and the declaration of smallpox eradication by the Thirty-third World Health Assembly in 1980 provided a strong incentive for laboratories not actively working with variola virus to destroy their stocks or transfer them to one of the WHO collaborating centres that was equipped with a high-security containment laboratory. By the end of 1981, only 4 laboratories still retained variola virus stocks: one each in South Africa, the United Kingdom, the USSR and the USA. Except for the South African laboratory, all were WHO collaborating centres for the diagnosis of, or research on, orthopoxvirus infections.

Between 1979 and 1982 Dr Keith Dumbell, a member of the Committee on Orthopoxvirus Infections, was engaged in research on variola virus, including the cloning of its DNA, in the biocontainment laboratory at the Centre for Applied Microbiology and Research, Porton Down, England. With the completion of this work in September 1982, all the variola virus stocks held at Porton Down were transferred to the Centers for Disease Control, Atlanta.

# Smallpox virus destroyed

VARIOLA, that is smallpox isolates contained in 177 vials were destroyed at the P4 high security laboratory at the South African National Institute for Virology in Johannesburg on 9 December 1983.

Previously the deadly virus had been stored in three centres, i.e. the Centre for Disease Control in Atlanta, USA, the Russian Institute for Virus Production in the USSR, and the SA National Institute for Virology. The South African laboratory had been approved and regularly inspected by the World Health Organisation, the last inspection having been in February 1983.

Because research regarding the genotype mapping of the smallpox virus had been completed and it was no longer required for the preparation of vaccine or other research, there was no reason for keeping the virus here any longer.

Normally the virus had been stored at 20°C and in order to destroy all the isolates the vials were placed in an autoclave and submitted to 130°C and 240 kpa for 20 minutes. Copies of all the isolates are, however, still available at the Centre for Disease Control in Atlanta.

The last known natural case of smallpox occurred in October 1977 in Somalia, and in 1980 the WHO de-

Prof Keith Dumbell, (left) former member of the World Health Organisation Committee on the Global Eradication of Smallpox was present to witness the destruction of all the virus. With him is Dr Bob Swanepoel, Senior Virologist in charge of the P4 Laboratory.

clared the world free of the dreaded disease.

Dr The Honourable C V van der Merwe, Minister of Health and Wel-

fare officiated and pressed the button to set the destruction process in motion. It was also done in the presence of Prof Keith Dumbell, an

observer and former member of the World Health Organisation Committee on the Global Eradication of Smallpox.

**Plate 28.4.** Destruction of variola virus stocks at the National Institute for Virology, Sandringham, South Africa, on 9 December 1983. The operation was carried out by the Minister of Health and Welfare of South Africa and witnessed by Dr K.R. Dumbell (left), a member of the Committee on Orthopoxvirus Infections and Dr Bob Swanepoel (right), Senior Virologist in charge of the P4 Laboratory.

In South Africa, the National Institute for Virology in Sandringham retained locally isolated strains of variola virus in a high-security biocontainment laboratory, although they had not been used for many years. Because of South Africa's political isolation, the health authorities were afraid that, if the virus were destroyed, they would have difficulties in diagnosing variola virus should any unexpected circumstances occur. However, when cloned preparations of fragments of variola virus DNA (which cannot replicate and are completely safe to work with) were made available to the National Institute for Virology by Dr Dumbell, their anxieties were relieved and the South African government destroyed all virus stocks in December 1983, in the presence of Dr Dumbell (Plate 28.4).

Since the beginning of 1984, stocks of variola virus have been retained only in the WHO collaborating centres in the Centers for Disease Control, Atlanta, USA, and the Moscow Research Institute for Viral Preparations, USSR, each of which possesses a high-security biocontainment laboratory. During 1983, the remodelling of these laboratories was completed, and both were approved by WHO inspection teams for work with variola virus. The retention of these facilities and their associated personnel has been costly, but the governments of the USSR and the USA have continued to provide the necessary support because of their value in examining material from cases of human monkeypox and from suspected cases of smallpox referred to them through the international rumour register.

The stocks held at the Centers for Disease Control include those transferred from the National Institute of Health, Japan; the National Institute of Public Health, Netherlands; the Centre for Applied Microbiology and Research, United Kingdom; the American Type Culture Collection, New York; and the United States Army Medical Research Institute for Infectious Diseases, Frederick, Maryland, USA. In addition to variola virus stocks, the Moscow laboratory holds "white-pox" viruses isolated from animal specimens and from monkeypox virus stocks (see Chapter 30). These virus stocks are regarded as just as dangerous as variola virus and are kept in the containment laboratory under the same security conditions as that virus. The variola virus stocks in Atlanta and Moscow contain strains of variola major and variola minor viruses from most areas in which smallpox has occurred since 1967.

In March 1986 the Committee on Orthopoxvirus Infections reviewed its policy on the retention of stocks of variola virus in the light of the existence of DNA from 5 strains of variola virus cloned in *Escherichia coli* and the current situation in relation to the use of the virus in research and diagnosis. The meeting was attended by senior public health officials from the two countries in which variola virus stocks are currently held—namely, the USSR and the USA. The Committee advised WHO that the cloned DNA would be satisfactory both for assisting diagnosis in any situation in which that might prove necessary and for archival purposes. Since the Committee considered that research work requiring the use of viable variola virus was no longer justified, it recommended that remaining stocks of the virus should be destroyed, and that this recommendation should be widely publicized but not implemented until approval had been

given by an *ad hoc* committee of experts, which it suggested should be convened by WHO (*Wkly epidem. rec.*, 1986b).

### Inspection

Since 1978, WHO inspection teams consisting of epidemiologists, virologists and biosafety experts have periodically visited all the laboratories retaining variola virus, in order to determine whether each of them satisfied the relevant WHO requirements. Inspections have been made annually or every second or third year (Table 28.7), a special check-list being used to cover all safety aspects. These inspections have revealed that problems sometimes occur in the efficient operation of biocontainment laboratories, even though the personnel concerned are highly trained.

## HUMAN MONKEYPOX

"Human monkeypox is a rare zoonosis that was not recognized until smallpox was eliminated from the area where it occurs. Clinically it resembles smallpox. Human cases can be expected to appear where the ecological conditions are appropriate and perhaps to show some increase as smallpox vaccination ceases and immunity wanes. Because it is caused by a poxvirus distinct from variola virus and has a limited capacity to spread between humans, monkeypox virus does not constitute a threat to the permanence of smallpox eradication. However, it is important that close surveillance of human cases should continue and that further investigation should be made into the natural history of the disease.

*"Recommendation (11).* In collaboration with country health services, WHO should organize and assist a special surveillance programme on human monkeypox, its epidemiology, and its ecology in areas where it is known to have occurred. The programme should continue until 1985, when a further assessment of the situation should be made".

The demonstration that monkeypox virus caused sporadic infections in man was an important scientific discovery directly attributable to the smallpox eradication programme. Consideration of the ecology of the disease indicated that it was not a new, but a newly discovered, one. The implementation of recommendation (11) of the Global Com-

mission constituted the greater part of the post-smallpox-eradication programme. The organization of surveillance is described below and the results of these studies are reported in Chapter 29. Activities relating to human monkeypox were planned by Arita and Ježek, and implemented by the joint efforts of WHO, national staff in western Africa and Zaire, and the WHO collaborating centres.

### Epidemiological Surveillance in Zaire

Work in Zaire from 1980 onwards built on the surveillance system established there in the late 1970s (see Chapter 29).

#### *Seminar in Brazzaville, May 1980*

A seminar on the surveillance of monkeypox and viral haemorrhagic fevers was held in the WHO Regional Office for Africa, Brazzaville, Congo, in May 1980. Its objective was to devise ways of further strengthening the surveillance of monkeypox and viral haemorrhagic fevers in areas of central and western Africa in which these zoonoses occurred. WHO staff from Geneva and the regional office and delegates from 10 countries in central and western Africa and 2 countries in eastern and southern Africa participated in the seminar, which recommended that the health services of each country should develop special surveillance of these diseases. A document entitled *Procedures for the surveillance and management of monkeypox and viral haemorrhagic fevers* (CDS/80.1) was promptly prepared by WHO and widely distributed, but only 3 cases of monkeypox were reported in 1980 and 8 in 1981.

#### *Health-institution-based surveillance in Zaire*

In the summer of 1980, Arita visited Kinshasa, Zaire, to discuss with the health authorities and the staff of the monkeypox programme how to strengthen surveillance activities. A review of the previous 3 years of surveillance in Zaire revealed 2 important findings: (1) most of the cases reported were patients who had visited hospitals or dispensaries seeking medical treatment; and (2) an earlier recommendation that mobile surveillance teams should visit all health stations every 3 months had never been implemented because of limited resources. Furthermore,

### African Viral Haemorrhagic Fevers

In addition to smallpox and yellow fever, which were for centuries the commonest viral diseases with haemorrhagic manifestations, several other viral haemorrhagic fevers have been recognized in recent decades (McCormick & Johnson, 1984). All are presumed to be contracted by man from an animal source. Three of them, Ebola virus disease, Lassa fever and Crimean-Congo haemorrhagic fever, occur in central and western Africa. The natural history of Ebola virus, which caused a major outbreak in a hospital in Zaire in 1976, is unknown, and there are many gaps in our knowledge of the ecology of the other two diseases. In the studies planned in Zaire, surveillance for haemorrhagic fever was added to monkeypox surveillance, since the geographical areas in which these diseases have been identified overlap and the methods of investigation are similar. In this way the best use could be made of the sparse resources available in central and western Africa.

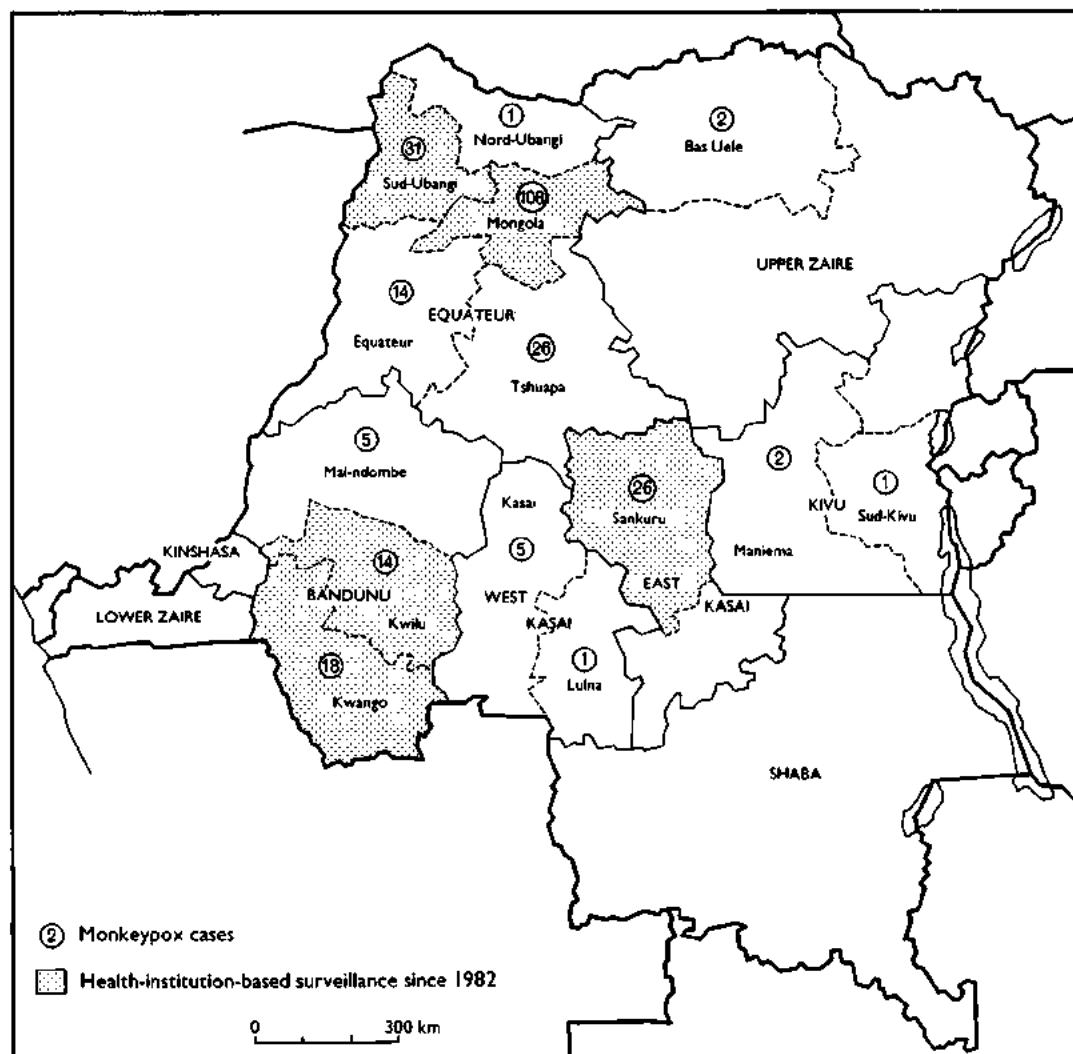

Fig. 28.1. Zaire: subregions where intensive health-institution-based surveillance has been carried out since 1982, and numbers of cases of human monkeypox by subregion, 1970-1984.

### Health-Institution-Based Surveillance

The idea of using health-institution-based surveillance for human monkeypox in Zaire stemmed from experience in western Africa with Lassa fever. This is a haemorrhagic fever caused by an arenavirus, which was first recognized in a hospital outbreak in Lassa, Nigeria, in January 1969. Outbreaks subsequently occurred in hospitals in several other parts of western Africa, and in the early 1970s it was thought to be a rare zoonosis, which was associated with a case-fatality rate of about 50% when outbreaks did occur. In 1977 a study was commenced in the Kenema District, Sierra Leone, under the direction of Dr Joseph B. McCormick, of the United States Center for Disease Control, to assess the prevalence and importance of Lassa fever. A surveillance system based on the hospital reporting of febrile disease was established, together with a small diagnostic laboratory. Local personnel were trained to take specimens from patients and to investigate any suspected cases of Lassa fever. The system was successful and showed that the disease was a common cause of hospital admission for both adults and children, with several hundred cases occurring annually in the area. The severity of cases varied greatly, with a case-fatality rate of less than 5% among subjects sick enough to report to hospital. The overall case-fatality rate was even lower, since other studies revealed that 6% of a population surveyed in Kenema District had complement-fixing antibodies against Lassa virus while only 0.2% had recognized disease (Fraser et al., 1974).

This experience suggested that health-institution-based surveillance might be a practical method for monitoring the prevalence of a disease in areas in which the infrastructure for public health and preventive medicine was rudimentary.

the mobile teams were frequently used in the control of cholera outbreaks. In the circumstances, health-institution-based surveillance, which was based on the collaboration of hospital and dispensary staff, appeared to be the most promising method of obtaining more information about human monkeypox. The system was concentrated in 4 subregions of 3 regions in northern Zaire, which had extensive areas of tropical rain forest and in which a relatively high incidence of the disease had been observed in 1978 and 1979.

Between December 1980 and November 1981, 4 seminars on monkeypox and viral haemorrhagic fever surveillance were organized by Ježek, in collaboration with Dr Kalisa Ruti, of the Ministry of Health of Zaire, in which medical staff from 154 health institutions participated. The seminars, which brought together all senior staff of health units working within a radius of 250–500 kilometres, were held in Lisala for Mongola subregion (December 1980), in Gemena for Sud-Ubangi subregion (February 1981), in Lodja for Sankuru subregion (June 1981) and in Kikwit for Kwango and Kwilu subregions (November 1981) (see Fig. 28.1). It

was the first time in central and western Africa that seminars had been devoted specifically to these newly discovered diseases, with the participation of senior government officials and technical experts. Monkeypox recognition cards, sample collection kits and the document *Instructions for health-institution-based surveillance of monkeypox and viral haemorrhagic fevers* (CDS/80.2) were distributed to participants. It was announced that a reward of 500 zaires (US\$90) was to be offered to any person, including health staff, who reported a case of human monkeypox.

Following each seminar, health-institution-based surveillance for human monkeypox and viral haemorrhagic fevers, supported by WHO funds, was developed in each subregion (Fig. 28.1), and by the end of 1981 was functioning effectively in all of them. The selected areas together represented about 15% of the land area of Zaire and contained about 5 million inhabitants—18% of the country's population—among whom 89% of the human monkeypox cases recorded in Zaire up to that time had been detected. Sporadic cases of Ebola haemorrhagic fever were also known to occur in some of the

selected areas. A total of 154 health establishments participated in surveillance activities, including 55 government and missionary hospitals, 62 dispensaries and 37 other health units (health centres and maternal and child health clinics). They were responsible for the discovery, identification and notification of suspected cases of monkeypox or viral haemorrhagic fever as well as the proper collection and dispatch of specimens for laboratory investigation. Their activities were supported by 4 mobile surveillance teams, which provided technical advice and material support. This well-designed and well-supervised surveillance system based on peripheral health units and mobile surveillance teams was supplemented by posting special surveillance officers in 4 areas of epidemiological priority to carry out village-based surveillance and assist in ecological surveys.

The striking increase in the number of monkeypox cases reported in Zaire in 1982 (39 cases) and 1983 (84 cases), as compared with previous years (see Chapter 29, Table 29.3), was due principally to the strengthened health-institution-based surveillance and intensified field activities, since 90% of the cases reported in Zaire in 1982-1983 were detected in areas of strengthened surveillance; and health-institution-based surveillance itself accounted for about 60% of the reported cases. The description of the clinical features and epidemiology of human monkeypox given in Chapter 29 is based on the results obtained by this intensive surveillance in Zaire, supported by laboratory studies in the WHO collaborating centres in Atlanta and Moscow.

#### *Serological survey of unvaccinated subjects*

In order to estimate the prevalence of human monkeypox in central and western Africa, serological surveys were conducted on unvaccinated subjects living in tropical rain forest areas of the Congo, Côte d'Ivoire, Sierra Leone and Zaire (see Chapter 29, Table 29.10). These surveys revealed that at least 0.7% of the persons concerned, who lived in areas in which monkeypox could be expected to occur, had specific antibody to it. Follow-up examinations of persons with positive serological findings indicated that over half of them had no history of a vesiculopustular disease or any facial pockmarks. It was concluded that at least some of them had suffered from a

subclinical infection with monkeypox virus (see Chapter 29).

#### *Studies on the ecology of monkeypox virus*

In 1984-1986, Dr Lev Khodakevich and his collaborators carried out surveys in the Central African Republic and Zaire in order to try to determine the reservoir host of monkeypox virus. These were successful in incriminating squirrels as a significant wild animal host of monkeypox virus in some areas (see Chapter 29).

### **Review of Monkeypox, March 1986**

In its review of the situation in March 1986, the Committee on Orthopoxvirus Infections noted that excellent progress had been made in understanding the epidemiology of human monkeypox and the ecology of monkeypox virus since its third meeting, in 1984. The results of these studies, described in detail in Chapter 29, indicated that human monkeypox was a rare zoonosis in which human-to-human infection sometimes occurred. The Committee concluded that it was now clear that the disease was not a serious public health problem and recommended that WHO involvement in monkeypox surveillance and research should be phased out (*Wkly epidem. rec.*, 1986b).

### **LABORATORY INVESTIGATIONS**

"There are still some important unsolved virological problems that are relevant to smallpox eradication, especially in relation to the 'white-pox' viruses. The solution of these problems and preparedness for unexpected problems that might arise in relation to smallpox or other poxvirus diseases of man call for the maintenance of suitable virological expertise.

"Besides encouraging scientists in various nations to continue research on orthopoxviruses, WHO has responsibility for the regular testing of the potency of the WHO vaccine reserves and for the provision of laboratory diagnostic facilities for suspected smallpox cases. It can best discharge this responsibility by continuing the system of WHO collaborating centres. If competent research workers from laboratories not approved by WHO for work with variola and whitepox viruses wish to conduct experiments with these viruses, facilities should, if possible, be provided by a suitable WHO

collaborating centre. These experiments must be approved by the appropriate WHO committee.

*Recommendation (12).* WHO should continue to encourage and coordinate research on orthopoxviruses.

*Recommendation (13).* WHO should maintain the system of WHO collaborating centres for carrying out diagnostic work and research on orthopoxviruses.

*Recommendation (14).* Research workers who do not work in a WHO collaborating centre and who wish to carry out experiments with variola or whitepox virus that are approved by the appropriate WHO committee should be offered the use of the special facilities in a WHO collaborating centre.

*Recommendation (15).* Research on poxviruses other than variola or whitepox viruses should not be performed under circumstances where there is any possibility of cross-contamination with these two agents."

### Laboratory Diagnosis of Suspected Smallpox and Monkeypox

Since 1980 the two WHO collaborating centres in Atlanta (Dr James Nakano, director) and Moscow (Dr Svetlana Marennikova, director) have continued the diagnostic testing of specimens collected from suspected cases of smallpox throughout the world, employing for this purpose laboratory workers with extensive experience obtained during the Intensified Smallpox Eradication Programme. In addition to examining material from some of the cases reported to the international rumour register, the centres examined specimens collected from suspected cases of human monkeypox and from other poxvirus infections (tanapox and molluscum contagiosum) in western and central Africa. Between 1980 and 1984, 16 650 specimens were tested (Table 28.8), the majority having been collected during serological surveys for human monkeypox. Requests for viral isolation came mainly from countries in which human monkeypox cases had occurred or were suspected, mostly as part of the special surveillance for human monkeypox described earlier in this chapter and in greater detail in Chapter 29. In addition, 193 requests were received from 28 other countries in connection with suspected cases of smallpox. In no case was variola virus found.

<sup>c</sup> Other countries (i.e., those not mentioned in footnote <sup>a</sup>).

<sup>d</sup> Includes 1433 specimens of serum from the Congo collected in serological surveys (see Chapter 29, Table 29.10).

### Continuing Research on Orthopoxviruses

Research problems of importance to WHO in the post-smallpox-eradication era fell into 3 categories: (1) analysis of the DNA of variola virus and other orthopoxviruses; (2) development of sensitive tests to detect antibody specific to monkeypox virus in human and animal sera; and (3) ecological and epidemiological research on the natural history of monkeypox.

#### *Analysis of orthopoxvirus DNA*

In June 1979, in view of the fact that the certification of global eradication was imminent, WHO organized a meeting on orthopoxvirus research, which was co-sponsored by the Centers for Disease Control and held in Atlanta (SME/79.9). The objective was to define fields of research relevant to the post-smallpox-eradication era. At that time there was still considerable controversy as to the significance of the "whitepox" viruses that had been isolated in laboratories in the Netherlands (Bilthoven), and the USSR (Moscow). Following discussions at the meeting, collaborative work with personnel from the Bilthoven and Moscow laboratories was carried out by Dr Dumbell at the Centre for Applied Microbiology and Research, Porton Down, and by Dr Joseph Esposito at the Centers for Disease Control. These studies showed that all strains of "whitepox" virus were identical with variola virus and probably originated as laboratory contaminants (see Chapter 30).

Dr Dumbell, Dr Esposito and their colleagues continued to carry out studies on the DNA of various strains of variola and monkeypox viruses, thereby considerably increasing our understanding of these viruses; the results of these studies are summarized in Chapters 2, 29 and 30. Dr Esposito also produced, for the first time, restriction endonuclease maps of the DNA of camelpox, taterapox and raccoonpox viruses, all of which are species of *Orthopoxvirus* (Esposito & Knight, 1985).

Both Dr Dumbell and Dr Esposito cloned variola virus DNA in *Escherichia coli*, rendering it safe to handle in any laboratory. By March 1986, libraries of cloned fragments of the DNA of 2 strains of variola major virus (Harvey and a strain from Bangladesh) and of 3 strains of variola minor virus (2 strains of alastrim virus and a strain from Somalia) were

available. At that time, the Committee on Orthopoxvirus Infections suggested that a western African strain should also be cloned, so as to provide a reasonable range of strains of variola virus DNA for archival purposes and for scientific research. It was because this material was or would be available that the Committee recommended the destruction of the remaining stocks of viable variola virus (see below).

#### *Development of tests for antibody specific to monkeypox virus*

The genus *Orthopoxvirus* includes 9 known species, of which 3 (vaccinia, monkeypox and taterapox viruses) or possibly 4 (with Uasin Gishu disease virus, an orthopoxvirus that affects horses in Kenya) occur in western and central Africa. All species of *Orthopoxvirus* show extensive serological cross-reactivity. Methods existed for making presumptive species-specific diagnoses of infections with monkeypox, variola and vaccinia viruses by tests on sera absorbed with viral suspensions, but their use with sera from healthy animals or man taken during ecological or epidemiological surveys gave uncertain results. It was therefore difficult to evaluate the significance of the large number of orthopoxvirus-positive sera obtained in ecological surveys in Zaire in 1979 and earlier (see Chapter 29). Consequently, there was an urgent need for a sensitive test for monkeypox-specific antibodies which could be used with sera collected during ecological and epidemiological surveys to support surveillance and field studies of human monkeypox. Such a test would also help to determine the extent of subclinical and person-to-person infection with monkeypox virus.

Several steps were taken to try to solve this problem. In 1981 Dr W. K. Joklik, of Duke University Medical Center, Durham, North Carolina, USA, attempted to develop a radio-immunoprecipitation test for the identification of monkeypox-specific antibody, but without success. Monoclonal antibodies that reacted with monkeypox virus but not with certain other orthopoxviruses were developed by Dr Y. Ichihashi in Dr Joklik's laboratory, and at the WHO collaborating centre in Atlanta, in 1983. Subsequently Dr Ichihashi continued work on monoclonal antibodies at Niigata University, Japan, with financial assistance from WHO; he developed a number of monkeypox-specific and vaccinia-

specific monoclonal antibodies and an antigen-binding inhibition test that could be used with certain sera to detect monkeypox-specific antibodies. However, at the time of writing this test requires further development.

Fortunately, in 1985 Dr Nakano developed modifications of the radioimmunoassay adsorption test which made it possible to evaluate the significance of some of the orthopoxvirus antibody-positive animal sera collected in Zaire in 1979 (see Chapter 29).

### Other Studies of Variola and "Whitepox" Viruses

Recommendation (14) envisaged the possibility that workers in laboratories other than the two WHO collaborating centres might wish to work with variola or "whitepox" viruses, but no such requests have been made.

Recommendation (15), designed to minimize the possibility of laboratory contamination with variola virus, has been rigorously observed in both WHO collaborating centres.

## DOCUMENTATION OF THE SMALLPOX ERADICATION PROGRAMME

"The eradication of smallpox is a unique event in human history and a signal achievement of WHO. It should be fully documented by the publication of a comprehensive book. Further, it is essential for future historians that all relevant

documents covering matters of scientific, operational, or administrative interest should be catalogued and preserved in suitable archives. The feasibility of distributing copies of this archival material to several centres, perhaps as microfiche, should be explored.

"It is important that the experiences of the smallpox eradication programme that are applicable to other health programmes should be defined and elaborated, in order to help public health officials develop strategies and tactics for the conduct of other programmes, especially those for the control of infectious diseases. However, the problem is complex since the lessons learnt from the smallpox eradication programme need to be evaluated in each instance by the health programme to which they may be applied.

"*Recommendation (16).* WHO should ensure that appropriate publications are produced describing smallpox and its eradication and the principles and methods that are applicable to other programmes.

"*Recommendation (17).* All relevant scientific, operational and administrative data should be catalogued and retained for archival purposes in WHO headquarters and perhaps also in several centres interested in the history of medicine."

### Publications

Planning for a comprehensive publication on all aspects of smallpox and recording its eradication had in fact begun in 1979 before recommendation (16) was made, and work on the present book started early in 1980. In addition, the WHO Regional Office for

**Plate 28.5.** Participants in the seventh meeting of the Editorial Board for *Smallpox and its Eradication*, 26 March 1986. Left to right: **A.D. Loveday (WHO)**, **K. Wynn (WHO)**, **I. Arita (Japan)**, **N. Henderson (USA)**, **S.M. Deck (WHO)**, **F. Fenner (Australia)**, **I.D. Ladnyi (USSR)**, **Z. Ježek (WHO)**, **D.A. Henderson (USA)**, **J.F. Wickett (WHO)**. The names of the Board members are in bold type.

South-East Asia published books dealing with the eradication programmes in India (Basu et al., 1979) and Bangladesh (Joarder et al., 1980); the government of Somalia and WHO jointly published the account of the programme in Somalia (Ježek et al., 1981); and the government of Ethiopia and the WHO Regional Office for the Eastern Mediterranean did likewise for the programme in Ethiopia (Tekeste et al., 1984). WHO also assisted in the preparation of a book dealing with the management aspects of the programme in India (Brilliant, 1985).

Recommendation (16) has also been implemented by the publication in WHO periodicals and elsewhere of numerous articles on smallpox and its eradication written by WHO staff and by other persons who were concerned with the eradication campaign. Reference to these is made throughout this book.

### The Smallpox Eradication Programme Archives

The smallpox eradication programme records were put in order by a professional archivist specifically employed for the purpose in 1981–1982. All WHO records prior to 1981 are now catalogued and indexed; they occupy 400 large boxes, which are stored in the Organization's archives at WHO Headquarters. Additional material, much of it voluminous and not available elsewhere, has accumulated since 1981. The Committee on Orthopoxvirus Infections suggested that it be added to the permanent archives.

### WHO HEADQUARTERS STAFF

"The foregoing recommendations cannot be carried out successfully without central coordination, which should be provided at WHO headquarters. Since it is expected that the Global Commission for the Certification of Smallpox Eradication will be dissolved after the World Health Assembly in 1980, another mechanism is needed to enable the headquarters staff to obtain advice and assistance from scientists. This could be achieved by setting up a committee on orthopoxvirus infections.

*"Recommendation (18).* An interregional team consisting of not less than two epidemiologists with past experience in the smallpox eradication campaign, plus supporting staff, should be maintained at WHO headquarters until at least

WHO / M. VANAPPELHEM

the end of 1985. At least one additional field officer should be assigned to cover areas where human monkeypox is under investigation.

*"Recommendation (19).* WHO should set up a committee on orthopoxvirus infections."

### Staff Arrangements at WHO Headquarters

The Smallpox Eradication unit, headed by Arita until March 1985 and then by Ježek, remained in being up to the end of 1987 with the requisite number of staff, including at various times Ježek (1980–1987), Dr A. Gromyko (1980–1983) and Dr L. Khodakevich (1983–1986) as medical officers, Mr J. Wickett (1980–1987) as consultant and Mrs S. Woolnough (1980–June 1985) as secretary. This unit, with its name unchanged, supervised the implementation of all the foregoing recommendations of the Global Commission, maintained the international rumour register, participated in the monkeypox studies in Zaire and in the preparation of publications, and organized meetings of the Committee on Orthopoxvirus Infections.

L. KHODAKEVICH, 1979

**Plate 28.7.** Alexander Gromyko (b. 1937), a physician from the USSR, worked for the Intensified Smallpox Eradication Programme as a WHO consultant in India in 1975 and then became a medical officer in the Smallpox Eradication unit (1977–1983). He participated in the monkeypox surveys in western Africa and in the investigation of rumours of smallpox reported to WHO.

### Committee on Orthopoxvirus Infections

A group of experts, all former members of the Global Commission, met in Geneva from 3 to 5 February 1981 to discuss the implementation of the post-smallpox-eradication policy. Subsequently the Director-General of WHO appointed this group as the WHO Committee on Orthopoxvirus Infections, with Fenner as chairman. In 1984, all 6 members were appointed for a second term of 2 years.

The Committee met annually and reviewed the situation in relation to all aspects of post-eradication activities (Global Commission recommendations 1–19). In 1984 the Committee undertook a comprehensive review of the human monkeypox programme, published a report on current knowledge of the disease (*Bulletin of the World Health Organization*, 1984), and made recommendations for future activities (WHO/SE/84.162). In 1986 it reviewed the operation of the post-smallpox-eradication programme and made recommendations on all its aspects. The Committee's report was published (*Wkly epidem. rec.*, 1986b) and widely circulated; its recommendations have been discussed in the relevant sections of this chapter.

Greenaway (United Kingdom), Y.L. Reznikov (WHO). The names of the Committee members are in bold type.

### USE OF VACCINIA VIRUS AS A VECTOR FOR FOREIGN GENES

The 19 recommendations made by the Global Commission in December 1979 effectively covered all aspects of orthopoxvirus infections then known to be important in the post-smallpox-eradication era. However, within 6 months, one of the members of the Global Commission, Dr K. R. Dumbell (Sam & Dumbell, 1981) discovered—and this was independently confirmed in the USA (Nakano et al., 1982)—that cells could be “transfected” with fragments of DNA from one orthopoxvirus, and that these fragments could be rescued by recombination when the cell was infected with another orthopoxvirus. It was only a short step from this to the insertion of genes coding for antigens inducing an immune response against one or more

of a variety of pathogens into plasmids in such a way that they recombined with vaccinia virus. The hybrid viruses thus produced were found to express antigens whose genes had been inserted in this way, and animal experiments showed that vaccination with them conferred protection against the infections concerned. This opened up the possibility that genetically engineered vaccinia virus might be used for immunization against a wide variety of protozoal, bacterial and viral diseases (Brown et al., 1986). WHO established a Scientific Advisory Group of Experts in 1984 to guide the work of a new Programme on Vaccine Development in which developments in the use of vaccinia virus are being monitored, together with the application of genetic engineering in the production of new vaccines.

### INTRODUCTION

Human monkeypox was first recognized in 1970; it is a severe systemic disease with a generalized pustular rash, clinically indistinguishable from smallpox. In addition to variola and monkeypox viruses, 7 other species of poxvirus, of 4 genera, can cause lesions in man (Table 29.1). Although infection with each of these viruses produces at the most

mild symptoms and usually only a localized skin lesion, the diseases in question presented a potential diagnostic problem during the global eradication of smallpox, since virus particles found in lesions by electron microscopic examination could be confused with those of variola virus. Because of its importance, monkeypox is the main subject of this chapter, but a brief description is given of each of the other poxvirus infections of man.

Table 29.1. Poxvirus infections of man

Genus and infection	Skin lesions in man	Severity of systemic symptoms	Host range in laboratory animals	Known reservoir hosts in nature
<i>Orthopoxvirus</i>				
Variola	Generalized	+++	Narrow	Man
Monkeypox	Generalized	+++	Broad	Squirrels, monkeys
Cowpox	Localized	+	Broad	Rodents
Vaccinia	Localized (very rarely, generalized)	+	Broad	Buffaloes <sup>a</sup>
<i>Parapoxvirus</i>				
Pseudocowpox	Localized	-	Narrow	Cattle
Bovine papular stomatitis	Localized	-	Narrow	Cattle
Contagious pustular dermatitis	Localized	-	Narrow	Sheep
Unclassified				
Molluscum contagiosum	Generalized	-	Narrow	Man
Tanapox	Localized	+	Narrow	Monkeys

<sup>a</sup> In 1984-1986, several years after the cessation of vaccination, epizootics of buffalopox were reported in several parts of India, and humans were infected. The virus involved was shown to be vaccinia virus (K. R. Dumbell, personal communication, 1986).

### MONKEYPOX IN CAPTIVE PRIMATES

Monkeypox virus was discovered in 1958, when it was isolated from the lesions of a generalized vesiculo-pustular disease among captive monkeys at the State Serum Institute, Copenhagen (Magnus et al., 1959). It was apparent that if an animal reservoir of variola virus existed the eradication of smallpox would be impossible (see Chapter 10). The close resemblance between smallpox and monkeypox in captive primates focused attention on monkeypox virus as a potential threat to smallpox eradication (Arita & Henderson, 1968). WHO therefore contacted laboratories in Europe and North America which used monkeys (27 in 1968 and 51 in 1970; Arita et al., 1972), inquiring about the occurrence of monkeypox and asking specifically whether any infections had occurred among laboratory workers or animal handlers. The ensuing investigations revealed 4 other reported outbreaks and 4 hitherto unreported outbreaks in primates (Table 29.2), but there were no reports of infection in humans. Monkeypox virus was recovered in 6 of these episodes. All except episode 3 occurred in Asian monkeys, although in some outbreaks African primates (and, in episode 2, New World monkeys) were also infected.

The circumstances of these outbreaks have been summarized by Arita et al. (1972). One episode described in their paper, but omitted from Table 29.2, calls for special comment—namely, the observation made by Gispén & Kapsenberg (1966) of the National Institute of Public Health in Bilthoven, Netherlands,

that monkeypox virus had been recovered from normal cynomolgus kidney cell cultures. Subsequent examination of the laboratory records led Dr J. G. Kapsenberg (personal communications, 1980, 1983) to decide that this isolation was probably due to inadvertent laboratory contamination of the culture with monkeypox virus, which had been isolated in the same laboratory at about this time from animals infected in the Blijdorp Zoo outbreak (episode 2).

Seven of the 9 outbreaks of monkeypox in captive monkey colonies between 1958 and 1968 occurred in monkeys shipped from Asia, leading to the suspicion that the reservoir of monkeypox virus was probably located in that continent. However, collaborative serological surveys organized by WHO failed to detect orthopoxvirus antibodies in over 1000 monkey sera collected in India, Indonesia, Japan and Malaysia (Arita et al., 1972). After the discovery of human monkeypox in Africa in 1970 (see later in this chapter), sera were collected from monkeys and other animals in Zaire and several countries of western Africa. Monkeypox-virus-specific antibodies were demonstrated in sera from 8 species of monkey and 2 species of squirrel, and monkeypox virus was recovered from the organs of a squirrel (see below).

Although primates from Asia, Africa and South America (and an anteater from the last-mentioned area) experienced infections with monkeypox virus in captivity, there is no evidence that the virus occurs naturally anywhere except in Africa. During the period 1958-1968 large numbers of primates were being imported into Europe and North

<sup>a</sup> Based on Arita et al. (1972).<sup>b</sup> .. = data not recorded.

America from Asia, and smaller numbers from western Africa, mainly for the manufacture and safety testing of poliomyelitis vaccines. At that time the conditions under which monkeys were moved from their place of capture in Asia or Africa to the recipient laboratory in Europe or North America presented many opportunities for them to be infected with agents carried by other wild animals or by man while in transit (Kalter & Heberling, 1971). The cessation of outbreaks after 1968 can be ascribed to improved conditions in the shipment of primates at about that time and the much more extensive use by laboratories of monkeys bred in captivity in Europe and North America.

The clinical features of naturally occurring cases in cynomolgus monkeys have been described by Magnus et al. (1959) and Sauer et al. (1960). No signs are detected until the rash

appears, usually as a single crop of discrete papules over the trunk and tail and on the face and limbs, being particularly abundant on the palms of the hands and the soles of the feet (Plate 29.1). The papules become vesicular and then pustular and are often umbilicated. Scabs develop and fall off 7–10 days after the onset of rash, leaving small scars. Circular discrete ulcers about 2 mm in diameter often occur in the oropharynx.

The severity of symptoms varied among the several different primate species infected in the outbreak of the Blijdorp Zoo in Rotterdam (episode 2, Table 29.2). All the species suffered from a generalized disease characterized by pocks on the skin, lips and mucous membranes. Orang-utans were particularly susceptible, several dying in the acute viraemic stage, before the skin lesions were fully developed.

**Plate 29.1.** Generalized lesions of monkeypox in a cynomolgus monkey. **A:** Acute stage; pustules on the leg and sole of the foot. **B:** Convalescent stage; healing pustules and scars. (From Magnus et al., 1959.)

## THE PROPERTIES OF MONKEYPOX VIRUS

In Chapter 2 the biological characteristics of monkeypox virus have been enumerated together with those of other orthopoxviruses (Table 2.3), and the restriction endonuclease map of monkeypox virus DNA has been compared with the corresponding maps of DNAs of other species of *Orthopoxvirus* (Fig. 2.6, 2.7 and 2.9).

### Pathogenicity for Laboratory Animals

Monkeypox virus has a broad host range and infects most of the common laboratory animals, producing moderate-sized haemorrhagic pocks on the chorioallantoic membrane and a large indurated swelling with a haemorrhagic centre after intradermal inoculation into rabbits (see Chapter 2, Plates 2.5 and 2.6). It produces lytic plaques in most kinds of cultured cells, but unlike variola

virus, it does not grow in pig embryo kidney cells when first cultured in them, although adaptation occurs quickly.

### Comparison of DNA Maps of Strains of Monkeypox Virus

Esposito & Knight (1985) analysed the DNA of 12 strains of monkeypox virus, 4 recovered from outbreaks in laboratory primates in Europe and North America and 8 from human cases in 4 countries in central and western Africa. The physical map locations of the sites of cleavage by the restriction endonuclease *Hind*III for the DNA of these strains of monkeypox virus, and the DNA of 2 strains each of variola and vaccinia viruses, are compared in Fig. 29.1.

As has been shown in the other comparisons described in Chapter 2, the DNAs of all strains of monkeypox virus are clearly different from those of both variola and vaccinia viruses. However, the monkeypox virus

### The Nomenclature of Poxvirus Diseases

For centuries it has been traditional to name poxvirus diseases after the animals in which they were first observed—for example, cowpox, horsepox, sheep-pox and fowlpox. The practice has continued in more recent times with the use of the terms monkeypox, rabbitpox, buffalopox, elephantpox virus to designate the viral agents recovered from infections of the animals concerned. Some of these designations are misleading. Thus it now appears that "cowpox" virus is primarily a disease of rodents, which has a wide host range and occasionally infects cows, cats, zoo animals and man. Rabbitpox and buffalopox are caused by strains of vaccinia virus, propagated in series in rabbits and buffaloes respectively. And although African monkeys are infected in nature with monkeypox virus, and may indeed be an important source of infection of humans, they are probably sentinel animals, only occasionally infected with this virus, rather than its principal reservoir host.

Fig. 29.1. Dendrogram illustrating the similarities and differences between the *Hind*III cleavage sites of the DNAs of 12 strains of monkeypox (Mpx) virus (McConnell and Washington are different passages of the same strain), 2 strains of vaccinia virus and 2 strains of variola virus. Presence, absence or impossibility of cleavage sites were analysed as described by Gibbs & Fenner (1984) using the squared Euclidean metric (number of attributes = 36). (Data from Esposito & Knight, 1985.)

DNAs cluster into 2 groups, according to the geographical origins of the specimens, rather than the animal of origin (man or monkey) or the year of isolation. The upper group of 4 in Fig. 29.1 are strains from human cases occurring in Zaire. The lower group consist of human isolates from 3 countries in western Africa—Nigeria, Liberia and Sierra Leone—and isolates from outbreaks in captive monkeys between 1959 and 1969. It is probable that all the outbreaks in captive monkeys (see Table 29.2) originated from western Africa

rather than Zaire, since exports of monkeys from Africa in the late 1950s and during the 1960s were from western African countries.

### Genetic Studies

Like other orthopoxviruses that produce haemorrhagic pox on the chorioallantoic membrane, monkeypox virus produces white pox mutants. These were first observed by Bedson (1964) and first reported by Gispén &

Brand-Saathof (1972). They were shown closely to resemble the parental monkeypox virus in tests for species-specific antigen (Gispen et al., 1976) and intracellular polypeptide patterns (Harper et al., 1979).

Subsequently it was reported that variants called "whitepox" viruses, which resembled variola virus by all biological tests, could be recovered from certain laboratory stocks of monkeypox virus, either by passage in hamsters (Marennikova & Shelukhina, 1978) or by inoculation on the chorioallantoic membrane (Marennikova et al. 1979). This initially raised important questions about a possible animal reservoir of variola virus, but these were subsequently discounted. By about 1982 accumulating evidence had convinced most laboratory workers that the "whitepox" viruses were in fact strains of variola virus inadvertently introduced as laboratory contaminants (see Chapter 30).

### Species Diagnosis

The biological characteristics used to identify monkeypox virus and, in material derived from human cases, to distinguish it from variola virus, are the haemorrhagic pox and high ceiling temperature on the chorioallantoic membrane, the production of a large haemorrhagic lesion after intradermal inoculation in rabbits, its wide host range and its failure to grow in pig embryo kidney cells when first inoculated into these cells. The DNA map is characteristic of the species, but can be used to distinguish western African from Zairian strains.

### Serological Diagnosis of Past Monkeypox Infection

An understanding of the ecology of monkeypox virus depends either on the isolation of virus from animals captured in the field or on serological surveys for monkeypox-virus-specific antibodies. The isolation of virus from animals captured in the field is likely to be a rare event in orthopoxvirus infections, in which persistent infection does not occur, and in fact only one such isolation has been made (see below).

During the 1970s methods had been developed that enabled species-specific diagnoses of recent infection with monkeypox, vaccinia and variola viruses to be made with

hyperimmune or other highly potent sera, by adsorption with appropriate viral suspensions and tests for residual antibody by gel precipitation (Gispen & Brand-Saathof, 1974), immunofluorescence (Gispen et al., 1976), radioimmunoassay (Hutchinson et al., 1977), and enzyme-linked immunosorbent assay (ELISA) (Marennikova et al., 1981) (see Chapter 3). For these tests, rather large quantities of high-titre serum were required, and for the radioimmunoassay adsorption test employed by the WHO collaborating centre in the Centers for Disease Control in Atlanta, GA, USA, antibodies to the gammaglobulin of the relevant species were thought to be necessary, which were available for monkeys but not for other species of wild animals.

However, as a result of experience with sera from persons known to have human monkeypox, some of whom had been vaccinated years earlier, Dr J. H. Nakano (personal communication, 1984) developed criteria that allowed a positive or presumptive diagnosis of monkeypox to be made in most suspected cases involving human sera. In mid-1985, Dr Nakano and Mrs Donna Miller (personal communication, 1986) developed a method of carrying out radioimmunoassay adsorption tests with sera from squirrels and some other species of wild animals, using staphylococcus A protein instead of a species-specific anti-gammaglobulin. This made it possible to test many animal sera from the field and has helped to elucidate the ecology of monkeypox virus.

## HUMAN MONKEYPOX

### Discovery of Human Infections

The first case of human monkeypox was found in the Basankusu Hospital, Equateur Province, Zaire (Ladnyj et al., 1972). The Basankusu Zone covers an area of about 20 000 square kilometres and in 1970 had an estimated population of 62 000, mostly primitive farmers and hunter-gatherers living in small villages in dense tropical rain forest. The last known outbreak of smallpox in Basankusu Zone occurred in 1968 and comprised 70 cases with 18 deaths. Several suspected cases of smallpox were treated at the hospital in 1969, but none was confirmed. Two suspected cases were reported in 1970; one of these turned out to be chickenpox, and the other was the first case of human monkeypox to be detected. The patient, a 9-month-

old boy, became ill with fever on 22 August 1970 and a rash developed 2 days later. He was admitted to hospital on 1 September, the 9th day of the rash, which had the characteristic centrifugal distribution of smallpox. Crusts were collected for laboratory examination and sent through WHO in Geneva to the WHO collaborating centre in the Moscow Research Institute for Viral Preparations, USSR. The patient recovered and was about to be discharged, but on 23 October he developed measles (acquired while in hospital) and died 6 days later.

During 1970 the WHO collaborating centre in Moscow had received a number of specimens from various provinces of Zaïre (but not from Equateur Province) from which variola virus had been recovered. The virus from Basankusu Hospital produced pocks on the chorioallantoic membrane that were quite different from those of variola virus. More detailed studies of this isolate, including inoculation in rabbit skin, showed that it was monkeypox virus (Marennikova et al., 1972a). Investigations of the epidemiological circumstances of the patient by Ladnyi

and Dr P. Ziegler in 1971 revealed that the child was the only unvaccinated member of his family, and that there had been no other cases of fever with rash recently in the village concerned or in neighbouring villages. Such an isolated case was most unlikely to be smallpox.

The discovery of human monkeypox in central Africa in September 1970 was followed by the demonstration that 4 cases of suspected smallpox in Liberia and 1 case in Sierra Leone in 1970, and 1 each in Nigeria and Côte d'Ivoire in 1971 (Foster et al., 1972) were cases of human monkeypox (Lourie et al., 1972). A series of coordinated laboratory and field studies was organized to determine the incidence of the disease, to study its clinical features and epidemiology and to search for the animal reservoir or reservoirs of the virus.

### Organization of Laboratory Research

In order to obtain guidance on what further research might be undertaken on the

**Plate 29.2.** Meeting of the Informal Consultation on Monkeypox and Related Viruses, Geneva, February 1976. Left to right, front row: T. Kitamura (Japan) C.I. Sands (WHO), C. Algan (WHO), F. Fenner (Australia), I. Arita (WHO), J.H. Nakano (USA); middle row: J.G. Breman (USA), R. Netter (France), E.A. Smith (Nigeria), S.S. Kalter (USA), I.D. Ladnyi (USSR), H.S. Bedson (UK), S.S. Henderson (WHO), K.R. Dumbell (UK), V.N. Milushin (USSR), A.C. Hekker (Netherlands).

### Recognition of Human Monkeypox in Central and Western Africa

Virologists interested in the poxviruses had known since 1959 that monkeypox virus could cause a generalized disease resembling smallpox in cynomolgus monkeys, and in the 1960s similar cases were recognized among other species of monkeys and in anthropoid apes. Although animal handlers had been exposed to risk during the several outbreaks among laboratory and zoo primates during the 1960s, there was at this time no indication that monkeypox virus would infect humans.

At the first meeting of the WHO Informal Group on Monkeypox and Related Viruses, in Moscow in March 1969, the experts agreed that the first indication that virus recovered from a skin lesion might be monkeypox virus would be the haemorrhagic appearance of the pocks produced on the chorioallantoic membrane after 3 days' incubation at 35 °C.

On 23 September 1970 Dr S. S. Marennikova, Dr E. M. Shelukhina and Dr N. N. Maltseva, of the WHO collaborating centre in Moscow, recovered a virus on the chorioallantoic membrane from material sent from a patient in Zaire. When examined after incubation for 2 days, the pocks were "perfectly typical" of variola virus. However, after another day's incubation at 35 °C, there was some haemorrhage around the pocks, a feature never seen with variola virus and characteristic of monkeypox virus. Further tests showed that, like monkeypox virus and unlike variola virus, the Zaire isolate produced large lesions in the rabbit skin.

Meanwhile, a diagnosis of variola virus had been made in the WHO collaborating centre in Atlanta with material obtained from 2 cases of smallpox-like disease discovered in different parts of Liberia in mid-September. This diagnosis caused great concern, since Liberia was thought to have been free of smallpox since 1969. Having learned of the occurrence of human monkeypox in Zaire, Henderson suggested to the WHO collaborating centre in Atlanta that the Liberian isolates should be carefully examined by appropriate tests to see whether they might be monkeypox virus. The Liberian isolates, and subsequent isolates from Sierra Leone and Nigeria, were then found to have the characteristics of monkeypox virus (Lourie et al., 1972).

Arrangements were made for further examination of both the Zaire and the Liberian isolates by Dr Keith Dumbell in London and Dr Rijk Gispens in Bilthoven, as well as in the WHO collaborating centres in Atlanta and Moscow. Work on these isolates formed the main topic of discussion at the second meeting of the Informal Group on Monkeypox and Related Viruses in February 1971. The experts attending that meeting agreed that these isolates were indeed monkeypox virus. This conclusion was a source of considerable relief, since it excluded the possibility that smallpox had been recurring in the most unlikely epidemiological situations; yet it also caused some concern, in that a new generalized orthopoxvirus disease of man had been discovered, the public health importance of which was unknown.

problem of monkeypox and to find out whether there was any evidence of an animal reservoir of variola virus, the WHO Smallpox Eradication unit organized informal discussions on monkeypox virus studies among a group of virologists, which met first in Moscow from 26 to 31 March 1969. These experts agreed that monkeypox virus could be readily distinguished from variola and vaccinia viruses by its biological characteristics, and further studies were planned on its morphology and behaviour in experimentally infected primates, and on the use of serologi-

cal tests to determine its geographical distribution.

The discovery of human monkeypox, and the subsequent reports that a variola-like virus ("whitepox" virus) had been recovered from the organs of animals captured in areas of Africa in which human monkeypox cases had occurred (see Chapter 30), clearly called for expert advice from virologists. Further meetings of the Informal Group on Monkeypox and Related Viruses were therefore arranged. In all, 5 more meetings were held, in 1971, 1973, 1976, 1978 and 1979, and were

attended by a total of 32 scientists from laboratories in 10 countries, including the WHO collaborating centres in Atlanta and Moscow as well as other collaborating centres conducting poxvirus research, in Bilthoven, Birmingham, London, Paris and Tokyo. In addition, field workers from 5 countries in central and western Africa and representatives from the WHO Regional Office for Africa, in Brazzaville, Congo, attended some of the meetings. Laboratory research on monkeypox, variola and "whitepox" viruses was carried out in the laboratories of the scientists who attended the meetings, sometimes with financial assistance from WHO.

### Organization of Field Research

To determine the most effective way of conducting the field research, the Smallpox Eradication unit organized a coordination meeting of representatives from central and western African countries in the WHO Regional Office for Africa, in October 1976, to assess the epidemiological situation in relation to human monkeypox, to draw up procedures for field surveys and to assess the sensitivity of epidemiological surveillance. It was clear from the data presented at this meeting that the best surveillance programme was that conducted in Zaire, the only country in the region in which smallpox surveillance had been maintained until eradication was certified in 1977 (see Chapter 25). Following a recommendation of the coordination meeting, an intensive surveillance programme was set up under the leadership of Dr Kalisa Ruti of the Ministry of Health of Zaire and Mr M. Szczeniowski, a WHO technical officer, in a geographically limited area in the northern part of Zaire (Ecuator Region, Mongala Subregion), in which a high concentration of human monkeypox cases had been observed.

This activity was extended in 1979–1980; and in May 1980 the Thirty-third World Health Assembly accepted the recommendation of the Global Commission for the Certification of Smallpox Eradication that further research was needed to determine the public health importance of human monkeypox. Field activities in Zaire were strengthened (see Chapter 28), and laboratory support was provided by the WHO collaborating centres in Atlanta and Moscow. The description in the following pages of the clinical features and epidemiology of human monkeypox and the ecology of monkeypox virus is

based on these studies, carried out over approximately a decade but most intensively in the years 1982–1986.

### Incidence and Distribution

Just over 400 cases of human monkeypox were reported between 1980 and 1986, all of which occurred in tropical rain forest areas of central and western Africa. At the time of writing, detailed analyses were available of the 283 cases reported between 1970 and 1984 (Fig. 29.2; Table 29.3). Of these, 89% were in small villages (under 1000 inhabitants) and 10% in larger villages (1000–5000 inhabitants); only 3 cases were reported in towns of over 5000 inhabitants. Even the last-named population groups had ample opportunities for direct contact with animals killed in the rain forests.

Between 1972 and 1981, the cases reported from Zaire greatly outnumbered those reported from any other country (Table 29.3), probably because the number of people living in villages in tropical rain forests is much larger there. From 1982 onwards many more cases were reported from Zaire than in previous years. This was partly due to the intensive surveillance system that had been developed in enzootic foci in that country,

Z. JEZEK, 1981

but there appears to have been a real increase in the incidence in 1983 and 1984. The reason for this increase is still uncertain. It may have been attributable in part to the fact that there were many more unvaccinated children than in earlier years, and in part, perhaps, to fluctuations in the extent of infection in the animals from which human infections were acquired.

### Clinical Features

A description of the clinical features of human monkeypox based on 47 cases diagnosed up to the end of 1979 (Breman et al., 1980) needs little revision in the light of experience since then (Arita et al. 1985). Clinically, human monkeypox closely resembles discrete ordinary-type or, occasionally, modified-type smallpox, as described in Chapter 1. No case has yet been seen, among the cases diagnosed in the years 1970–1984, with confluent lesions on the face, nor has any case comparable to flat-type or haemorrhagic-type smallpox been diagnosed. The obvious clinical feature that differentiates human monkeypox from smallpox is the pronounced lymph-node enlargement seen in most cases of monkeypox (Plates 29.4 and 29.5), sometimes only in the neck or inguinal region, but more often generalized. Lymph-node enlargement occurs early, and has often been observed at the time of onset of fever, usually 1–3 days before the rash appears. Lymph-node enlargement was observed in 90% of 98 cases in which its presence or absence was recorded and was a presenting sign, preceding the rash, in 65% of these cases.

The eruption begins after a prodromal illness lasting 1–3 days, with fever, prostration and usually lymph-node enlargement. As with smallpox, the lesions develop more or less simultaneously and evolve together at the same rate, through papules, vesicles and pustules, before umbilicating, drying and desquamating. This process usually takes about 2–3 weeks, depending on the severity of the disease. The distribution of the rash is mainly peripheral. Severe eruptions can cover the entire body (Plate 29.4), including the palms and soles. Most pustules are about 0.5 cm in diameter but some have been seen up to 1 cm in diameter. Lesions have been noted on the mucous membranes, the tongue and genitalia. One patient, who had been vaccinated several years previously, developed only

1 lesion, further emphasizing the fact that some cases can be exceedingly mild and would go unreported in the absence of active surveillance. As is described below, subclinical cases also occur, in unvaccinated as well as vaccinated subjects.

### *Sequelae*

As in smallpox, pitting scars may develop, most frequently on the face, but they tend to diminish in prominence with time. Secondary infection of the lesions is common and this may play a role in scarring. About half of the scars from lesions seen initially on the face and body were detectable 1–4 years after the acute illness. Desquamation of crusts leaves areas of hypopigmentation (Plate 29.5 B). Hyperpigmentation follows after a few months (Plate 29.4 D) and usually diminishes with time. In some cases large shallow residual scars are seen, and in a few cases corneal lesions have caused unilateral blindness.

### *Laboratory confirmation*

Throughout the investigations, great importance was attached to obtaining laboratory confirmation of the clinico-epidemiological diagnoses, initially because of the possible occurrence of smallpox and later because of the suspicion that “whitepox” virus (see Chapter 30) might infect humans. All laboratory diagnoses were made in the WHO collaborating centres, with the results shown in Table 29.4. The methods of laboratory diagnosis were those used for smallpox, supplemented by serology in cases in which viral isolation was not possible. This combination allowed positive diagnoses to be made in the great majority of cases. In spite of unavoidable delays in the collection and transmission of specimens, the percentage of recoveries of virus from samples taken from cases eventually diagnosed as human monkeypox was high. Virtually all the cases found positive by electron microscopy were also found positive by culture, and vice versa, but 60 (22%) of the cases were seen too late to obtain lesion material and could only be confirmed serologically. Retrospective diagnosis by serology was unequivocal in unvaccinated subjects but sometimes less clear in vaccinated persons, although with the experience gained over the past few years diagnoses are now possible in these cases also.

**Plate 29.4.** Human monkeypox in a 7-year-old Zairian girl. **A, B, C:** Acute stage, day 7 of rash. Note bilateral inguinal lymphadenopathy and enlarged submaxillary lymph nodes on right side. Pustular lesions on lips (**B**) also occur inside the mouth as ulcerated lesions: the enanthem. **D:** Same subject, 4½ years later. There are several hyperpigmented spots and facial pockmarks; in about half the cases of monkeypox these disappear within 5 years of the attack.

Total	172	179	176

#### Severity and case-fatality rates

On the basis of the number of skin lesions and the severity of systemic symptoms, cases in Zaire were classified as mild, moderate or severe (Table 29.5). The majority of cases (53.1%), and the majority of severe cases among the unvaccinated (58.3%), occurred among unvaccinated children in the age group 0-4 years. The 28 deaths all occurred in children between 7 months and 7 years of age (overall case-fatality rate among unvaccinated subjects, 11.3%), the case-fatality rate for the age group 0-4 years (14.3%) being almost twice that in unvaccinated children aged 5-14 years (7.7%).

Few cases were diagnosed in vaccinated subjects, only 30 of the 277 patients (10.8%) having a visible vaccination scar. The youngest of these was a 5-year-old boy who had been vaccinated shortly after birth and developed monkeypox late in 1983—i.e., about 5 years after vaccination.

#### Subclinical infections

Some cases of monkeypox in vaccinated subjects were extremely mild, with very few skin lesions. By analogy with smallpox (Heiner et al., 1971a; see Chapter 1), it was to be expected that many infections in vaccinated subjects would be subclinical. A more important question was whether inapparent infections occurred in unvaccinated human subjects. Data pertaining to this problem emerged from the intensive surveillance activities in Zaire in 1982-1984 (Ježek et al., 1986b). During that period 2510 contacts of 131 confirmed cases of human monkeypox were examined and questioned, often on several occasions. Sera were taken from 70% of the unvaccinated contacts and 6% of the vaccinated contacts and tested at the WHO collaborating centres in Atlanta and Moscow (Table 29.6). The laboratory tests showed that 91 (16%) of the contacts examined had been infected with monkeypox virus. Sixty of the 73 cases in unvaccinated contacts had a history or lesions compatible with human monkeypox, and 40 of them appeared to be secondary cases resulting from transmission of infection from another human case. The other 13 unvaccinated subjects (18%) gave no history and had no lesions suggestive of human monkeypox and must therefore be classed as cases of subclinical infection. The majority of such cases occurred in children aged between 2 and 10 years who had been household contacts of a severe case of human monkeypox. Only 1 subclinical case was recognized in a vaccinated subject, a 20-year-

<sup>a</sup> Based on Ježek et al. (1986b).

old man, but no special effort was made to detect subclinical infections among vaccinated subjects in a way comparable to the studies of Heiner et al. (1971a) with variola major in Pakistan.

Large-scale serological surveys of unvaccinated persons in Zaire (Ježek et al., 1987a; see later in this chapter) also revealed a few cases of subclinical infection.

### Epidemiology

Although the clinical features of human monkeypox are very similar to those of discrete ordinary-type smallpox, the epidemiology is quite different. Human monkeypox occurs mainly as single or occasionally multiple sporadic cases, in small villages in dense tropical rain forest in a limited part of Africa, among villagers who are engaged for at least part of their time as hunters and gatherers. Human monkeypox is a zoonosis which is usually contracted from a wild animal. However, human-to-human infection does occur in a minority of cases.

Two observations in the early 1980s deserve comment. Mutombo et al. (1983) reported a bizarre case in which a 6-month-old infant in a small village in the tropical rain forest in Zaire was abducted by a chimpanzee but rescued after sustaining a superficial wound on the lower leg and a fractured femur. The infant developed typical monkeypox, fever beginning 6 days after the incident and a rash 7 days later. Monkeypox virus was isolated from crust material. Lymphadenopathy began in the left inguinal region and

eventually became generalized, but the time of its appearance in relation to other symptoms could not be determined. Although not proved, it is a reasonable hypothesis that the infant acquired monkeypox from the chimpanzee.

The other observation concerns monkeypox among Pygmies who live in the tropical rain forests in the southern part of the Central African Republic, adjoining Zaire, in which Khodakevich et al. (1985) discovered a cluster of 5 cases of monkeypox, confirmed by virus isolation. The Pygmies who lived in the rain forests readily recognized the disease when shown a monkeypox recognition card, whereas the Bantus and Pygmies who lived in agricultural settlements had never seen a disease like it. Interrogation through interpreters revealed that the forest Pygmies had a special name for the disease and believed that it was acquired from animals and not from humans.

### Age and sex distribution

The ages of patients in Zaire varied between 6 months and 53 years, but the majority were children. The two sexes were equally affected; of 283 cases reported by the end of 1984, 51.3% were in males and 49.7% in females. When analysing the epidemiology of human monkeypox it is useful to distinguish between infections acquired from an animal source (primary cases) and those due to person-to-person infection (secondary cases) (Table 29.7). The vast majority of cases in both groups occurred in children, but cases in adults tended to be more

Table 29.7. Human monkeypox: the age incidence of primary and secondary cases in Zaire, 1982-1984

Age group (years)	Primary cases <sup>a</sup>		Secondary cases <sup>b</sup>	
	Number	%	Number	%
0-2	41	28.3	21	31.8

<sup>a</sup> Presumed to have been infected from an animal source.<sup>b</sup> Presumed person-to-person infection.

common among persons infected by contact with other human cases, usually mothers infected by sick children.

#### Seasonal distribution

Breman et al. (1980) reported a preponderance of cases in Zaire in the dry season, but with the institution of more intensive surveillance since 1982 the incidence of cases has been found to be much the same throughout the year. During the period 1982-1984 the monthly incidence of primary cases varied a good deal from year to year (Table 29.8); there was no clearly evident seasonal pattern. Secondary cases showed the same absence of a seasonal effect, although, as with primary cases, the incidence was low in October.

#### Sources of infection of sporadic cases

Epidemiological investigations in Zaire indicated that wild animals were the probable source of infection for some 70% of patients, and person-to-person infection was suspected in the remaining 30% (see Table 29.8). Since

monkeypox virus has a wide host range and evidence of infection in African wild animals has been obtained from chimpanzees, several species of monkey and 2 species of squirrel, the disease is probably transmitted to humans by more than one species of wild animal. It was virtually impossible to determine by case-control studies which animals might have been involved because the whole population in affected localities had multiple daily contacts with the same varieties of wild animals, in the settlements, agricultural areas or near-by forests. Species with which patients had multiple close contacts (within 3 weeks before the onset of rash), through hunting, skinning, playing with the animals or eating the carcasses, included various types of monkeys (65%), squirrels (12%), antelopes and gazelles (12%), terrestrial rodents (9%) and other animals (3%). Seventy-one per cent of suspected monkeys associated with patients belonged to the genus *Cercopithecus*, 12% to *Colobus* and 8% to *Cercocebus*. Two-thirds of suspected rodents were squirrels and the rest were *Cricetidae*. The majority of animals suspected of being the source of infection were apparently healthy.

The small villages in tropical rain forests, in which cases of human monkeypox occur, are usually not closely surrounded by high forest on all sides. A common situation is that they consist of groups of houses along roads through the forests, with extensive agricultural areas around the settlement itself, consisting of gardens and secondary forest, often with many oil palms, which provide food much favoured by certain squirrels. Beyond this, perhaps 3-5 kilometres away, is the primary rain forest. Each of the 3 zones—settlement, agricultural area, and forest—has a characteristic fauna. Domestic animals and commensal rodents frequent the immediate

<sup>a</sup> Presumably infected from an animal source.

environs of the houses, terrestrial and arboreal rodents and bats are found in the agricultural areas, and larger animals, including monkeys, inhabit the rain forest itself (Khodakevich et al., 1987a).

The various age groups of the population differ in the degree to which they move in and out of these areas. Children below the age of 2 years are rarely let out of their mother's sight; between the ages of 3 and 5 years they accompany their mothers to the agricultural area, and after the age of 5 years they go on their own to this area and hunt for small animals. Only the men and boys over 15 years of age hunt in the forest for large animals, including monkeys, antelopes and porcupines. Persons of all age groups would be exposed to infection from wild animals brought to the household for food. Those who might conceivably be exposed to an additional risk are the hunters and children old enough to capture small animals such as squirrels and rats in the agricultural areas. Very few primary cases have occurred in hunters, whereas children aged between 5 and 9 years have contracted many primary infections but a somewhat lower proportion of secondary infections (see Table 29.7). This may be related to the relatively high incidence of infection among squirrels captured in the agricultural areas (see below).

#### *Person-to-person spread*

The largest proportion of cases of monkeypox (48%) have occurred as single sporadic infections. However, sometimes cases have occurred in clusters, suggesting either multiple infections from a common source—co-primary cases—if the dates of onset lay within the presumed minimum incubation period of 7 days) or person-to-person transmission. The distribution of single sporadic cases, pre-

sumed co-primary cases and presumed secondary or subsequent person-to-person infections in Zaire in 1982-1984 is shown in Table 29.9. Intervals of 7 and 23 days between the dates of appearance of the rashes in persons in close family contact have been taken as the limits for presumed person-to-person spread. In the 3 years during which intensive surveillance was operating in Zaire, 66 out of 210 cases (31.4%) appeared to have been due to transmission from person to person. Examples of the type of pattern observed are shown in Fig. 29.3. An extreme example involving 4 probable successive person-to-person infections has been described by Ježek et al. (1986a).

If all these presumed cases of person-to-person infection are accepted as such, the secondary and later generation attack rate was 15.7% among unvaccinated household contacts and 0.6% among vaccinated household contacts. The secondary and later generation attack rate among those having casual face-to-face contact with patients was 3%. These figures are much lower than those for smallpox, in which the overall first generation secondary attack rates in household contacts were 58.4% for unvaccinated persons and 3.8% among vaccinated contacts (see Chapter 4, Table 4.12).

Using these data, which were obtained from a population in which the vaccination rate was about 70%, Ježek et al. (1987b) developed a stochastic model for person-to-person infections with monkeypox virus assuming overall vaccination rates of 50%, 25%, and zero. Although the expected numbers of generations and of cases infected by contact increased with the falling vaccination rate, the model suggested that the person-to-person infectivity of monkeypox was such that the disease always died out, after a maximum number, in the simulation,

Fig. 29.3. Some examples of presumed person-to-person transmission of monkeypox. All occurred among close family contacts, who lived in small villages in the tropical rain forest. Assuming that patients could remain infectious for about a week after the onset of the rash, the intervals between cases could be longer than the usual incubation period (assumed to be about 12 days, with a range of 7–19 days).

of 11 generations. This result supports an argument based on historical data—namely, that monkeypox virus has been enzootic in animals of the tropical rain forests in Zaire for centuries without ever establishing continuous person-to-person infection in a population that had been almost completely unvaccinated until about 1967.

*The prevalence of monkeypox virus infection in humans*

In an attempt to discover the prevalence of monkeypox virus infection of humans in tropical rain forest areas in various parts of central and western Africa, serological surveys of persons without vaccination scars were carried out in 1981 in the Congo and Zaire (central Africa) and Côte d'Ivoire and Sierra Leone (western Africa), according to a plan designed by Arita and Dr Joseph McCormick. Cases of monkeypox had been reported from all these countries except the Congo, which borders on Zaire and has a large area (over 21 million hectares) of tropical rain forest. Specimens of serum

collected from allegedly unvaccinated persons were tested in the WHO collaborating centres in Atlanta and Moscow, initially for vaccinia haemagglutination-inhibiting (HI) antibody, or by immunofluorescence at the Pasteur Institute in Abidjan, Côte d'Ivoire.

The results are shown in Table 29.10. Of 10 300 sera tested, 15.4% gave positive results by HI or immunofluorescence tests.

Supplementary examination of many of these sera by neutralization and ELISA tests showed good agreement with the results obtained with the HI or immunofluorescence test. The intention was to subject sera containing orthopoxvirus antibodies demonstrable by the screening test to further assay by either a radioimmunoassay adsorption test or an ELISA adsorption test. However, only 420 of the 1583 positive sera could be tested; of these, 73 gave results indicating that the subjects had been infected with monkeypox virus. None of the sera from the Congo gave a positive result by the ELISA adsorption test; the proportions of all sera designated as monkeypox-virus-positive varied from 0.70% for Côte d'Ivoire to 1.01% for Sierra Leone.

Table 29.10. Human monkeypox: results of serological survey among allegedly unvaccinated persons inhabiting villages in tropical rain forest areas of 4 countries of central and western Africa, 1981

Country	Number of sera tested	Positive by haemagglutination-inhibition or immunofluorescence test		Positive for monkeypox virus antibodies by radioimmunoassay adsorption		
		Number	Percentage	Number tested	Number positive	Percentage of total sera
Congo	1 433 <sup>a</sup>	231	16.1	78 <sup>b</sup>	0	0.0
Côte d'Ivoire	2 840	369	13.0	93	20	0.70

<sup>a</sup> Tested by enzyme-linked immunosorbent assay with monkeypox antigen.

<sup>b</sup> Tested by enzyme-linked immunosorbent assay adsorption.

Follow-up visits by Dr Alexander Gromyko and Dr Jean-Paul Ryst to Côte d'Ivoire and Sierra Leone in June–July 1982 to examine those who had monkeypox virus antibody in their sera showed that some specimens had inadvertently been taken from vaccinated subjects. However, none of the 13 subjects investigated had unequivocal evi-

dence of past vesiculo-pustular disease (by history or residual pockmarks). If any of them had been infected with monkeypox virus, as the serological results indicated, the infection was subclinical or so mild as to have been forgotten.

Because surveillance was much better in Zaire, it was possible to obtain more informa-

BY COURTESY OF Z. JEZEK

tion about the possible frequency of subclinical infection from the survey in Kote Zone, in which Ježek was able to visit some 400 localities, involving about 10 000 households and about 50 000 persons, who were examined for vaccination scars and facial pockmarks (Ježek et al., 1987a). Only 15% of those investigated had no vaccination scar, and 1.3% of them had facial skin changes suggesting a past attack of a vesiculo-pustular disease. Of a total of 3460 serum samples collected from persons without vaccination scars, 27 showed evidence of the presence of monkeypox-virus-specific antibodies by the radioimmunoassay adsorption test. The subsequent field investigation of 19 of these subjects, who were less than 15 years old, revealed that 12 of them had experienced vesiculo-pustular disease or fever with lymphadenopathy in the past, 1 had a possible vaccination scar, and the remaining 6 had no signs or history of a disease like human monkeypox. The prevalence rate of monkeypox-virus-specific antibodies showed significant differences in different age groups; it was 4 times higher in the children aged 5-9 years (13.1 per 1000) than in those aged 0-4 years (3.3 per 1000).

As with serological surveys among wild animals in Zaire, the lack of a serological test that is sufficiently sensitive and specific to permit the diagnosis of a previous monkeypox virus infection without resorting to serum adsorption has made it impossible to determine the prevalence of human infections with monkeypox virus from the results of these 4 surveys. The significance of the overall orthopoxvirus-positive antibody rate of 15.4% remains obscure; it may have been due to antibodies to vaccinia virus or to a "non-specific reacting material" (J. H. Nakano, personal communication, 1986). However, follow-up studies in 3 countries support the view that emerged from intensive surveillance in Zaire (see Table 29.6)—namely, that some infections of unvaccinated humans with monkeypox virus are subclinical.

### Ecological Studies

The epidemiology of primary cases of human monkeypox—i.e., those derived from an animal source—can be elucidated only from a knowledge of the ecology of the virus, involving the determination of which

animals act as reservoir and incidental hosts and the way in which the virus is transmitted from one animal to another. Initially, studies of this problem were focused on monkeys. Serological surveys of Asian monkeys were negative, but monkeypox-virus-specific antibodies were found in several species of monkeys that occur in central and western Africa.

Because members of each species of monkey usually move in small self-contained troops, and because monkeypox virus does not cause persistent infections and is not transmitted by flying arthropods, it seems unlikely that non-human primates are the reservoir hosts of the virus. From 1979 onwards, therefore, attention was directed to a wider range of wild animals, especially terrestrial and arboreal rodents, some of which occur in populations that remain sufficiently large to support enzootic monkeypox virus infection.

### *Serological survey of captive African primates*

Altogether 1447 sera of African primates held in various laboratories in Africa, Europe and the USA were tested for orthopoxvirus antibodies by either HI or neutralization tests; all were negative (Arita et al., 1972). With the possible exception of sera from 25 gorillas and 167 chimpanzees, all were obtained from animals captured in countries which have not reported cases of monkeypox, and the monkeys belonged to species occurring in the savanna rather than in tropical rain forests.

### *Serological surveys of primates from western Africa*

Breman et al. (1977c) examined primate sera that had been collected in western Africa for a yellow fever survey. HI and neutralization tests were done on 206 sera obtained from 27 different sampling zones in Côte d'Ivoire, Mali and Upper Volta (now Burkina Faso), which were situated in forest and heavily wooded preforest and in the savanna. Out of 195 sera, 15 (8%) were orthopoxvirus-positive by HI and 44 (23%) by neutralization tests. The testing of 3 HI-positive sera from forest-dwelling monkeys (1 *Colobus badius* and 2 *Cercopithecus petaurista*) by immunofluorescence after adsorption showed that they contained monkeypox-virus-specific antibodies (Gispen et al., 1976).

In another survey, 692 sera obtained from a variety of animals from Chad, Côte d'Ivoire, Liberia, Nigeria, Senegal, Sierra Leone, and Upper Volta between 1970 and 1972 were tested (J. H. Nakano, unpublished observations, 1973). One hundred and fifty-eight (23%) gave positive results by the HI test and 50 out of 186 (27%) were positive by neutralization. Among sera from non-human primates included in the 692 samples, 92 out of 334 (28%) gave positive HI results; 35 out of 147 sera tested by neutralization (24%) gave positive results. Positive HI titres were observed with occasional serum samples obtained from a variety of other animals, including squirrels, rodents, ungulates, and wart-hogs. Subsequently, 273 of the monkey sera were tested by radioimmunoassay adsorption tests. Seven sera contained monkey-pox-virus-specific antibodies: 2 from *Cercopithecus petaurista*, 2 from *Cercopithecus aethiops*, 2 from *Cercopithecus nictitans* and 1 from *Colobus badius* (J. H. Nakano, personal communication, 1986). The most interesting result was that obtained with *C. aethiops* from Côte d'Ivoire. Not only is this monkey typically an inhabitant of the savanna rather than the tropical rain forest, but it is the species that was exported from western Africa to North American and European countries on a large scale during the period when monkeypox was occurring in captive monkeys in these countries, and animals of

this species may have been the source of infection of Asian monkeys during transit.

Tissues from 648 animals of 73 species obtained in Liberia and Nigeria in 1971 were tested for orthopoxviruses by 2 serial passages in primary monkey kidney cells with negative results (J. H. Nakano, personal communication, 1983).

#### *Studies on material from Zaire, 1971-1979*

Since most cases of human monkeypox had occurred in Zaire, attempts to determine the reservoir host or hosts of the virus were subsequently concentrated in that country, mostly in places in which human monkeypox cases had occurred.

*Investigations by the WHO collaborating centre, Moscow.* Between 1971 and 1975 serological and virological investigations concerning a wild-animal reservoir of monkeypox virus were carried out at the WHO collaborating centre in Moscow. Some 200 sera from areas distant from what is now recognized as the monkeypox enzootic area (see Fig. 29.2) were virtually all negative, whereas monkey sera from Zaire collected in 1971 and 1973 showed 14 out of 81 positive by the HI test and 11 out of 65 by the neutralization test (Marennikova et al., 1975). Subsequently another collection of sera from Zaire yielded

24 HI-positive monkey sera out of 117 tested and 26 HI-positive rodent sera out of 245 tested.

Attempts were made to isolate virus on the chorioallantoic membrane from the kidneys of primates, rats, and squirrels collected in Zaire. None yielded monkeypox virus, but "whitepox" virus was said to have been obtained from 4 specimens and vaccinia virus from 1 specimen (see Chapter 30, Table 30.2).

*Investigations by the WHO collaborating centre, Atlanta.* In July 1979 a large-scale ecological survey in Zaire was organized by Dr Joel Breman, of the WHO Smallpox Eradication unit. Sera and organs were obtained from a wide variety of wild animals. The animal species were identified by expert zoologists and the sera and organs were tested at the WHO collaborating centre in Atlanta. In all, 1331 sera from 45 species of wild animals were tested by the HI test as a screening test for orthopoxvirus antibodies; 227 sera (17%), from a wide range of animals, gave positive results (J. H. Nakano, personal communications, 1983, 1986). All 50 sera from *Rattus* spp. were negative.

The subsequent testing of certain sera by radioimmunoassay adsorption tests cast doubt on the significance of the positive results obtained by the HI test, since none of 25 HI-positive sera of the squirrel *Heliosciurus rufobrachium* gave positive results by radioimmunoassay (Table 29.11). On the other hand, additional radioimmunoassay adsorption tests on monkey and squirrel sera from this

collection revealed positive results in 5 species of monkey and in squirrels of the genus *Funisciurus* (J. H. Nakano, personal communication, 1986).

Kidneys and spleens from 930 of the animals from the 1979 Zaire study, including all the monkeys, were passaged in Vero cells, and the monkey material was also tested on the chorioallantoic membrane, with negative results (J. H. Nakano, personal communication, 1983).

*Studies in Zaire, 1985-1986.* Ecological investigations in Zaire were renewed in 1985, under the direction of Dr L. Khodakevich. Attention was concentrated on animals found around the houses and in the adjacent agricultural area near villages in which cases of human monkeypox had recently occurred. An early and exciting result was the recovery of monkeypox virus from a diseased squirrel (*Funisciurus anerythrus*) (Khodakevich et al., 1986). This species of squirrel is quite common in the agricultural areas adjoining villages, where it feeds on oil palm seeds.

Subsequent studies on sera from terrestrial rodents and goats found near houses and squirrels found in the agricultural area revealed many monkeypox-virus-specific sera in 2 species of squirrel (*Funisciurus anerythrus* and *Heliosciurus rufobrachium*), but none in the other animals (Table 29.12; Khodakevich et al., 1987b). Investigations into the significance of the squirrel, *Funisciurus anerythrus*, as a possible reservoir host of monkeypox virus are proceeding as this book goes to press.

## MONKEYPOX: THE OVERALL PICTURE

Laboratory studies show that monkeypox virus is a distinct species of *Orthopoxvirus*. First reported as the cause of epizootics among captive monkeys in laboratory colonies in Europe and the USA and in an epizootic in a zoological garden in the Netherlands, it was found in 1970 to be the causative agent of a generalized human infection that clinically resembled smallpox.

Unlike smallpox, however, human monkeypox occurs only in persons living in small villages in tropical rain forests in central and western Africa, where hunting is an important method of obtaining food. The vast majority of reported cases have been found in Zaire, during an intensive surveillance campaign based on health institutions that has been in operation there since late in 1981. The majority of cases can be attributed to infection from an animal source, but person-to-person infection sometimes occurs, mainly between unvaccinated children. The longest chain of transmission observed so far is an incident in which there appeared to be 4 serial person-to-person infections (Ježek et al. 1986a). It seems likely that any of several animal species (chimpanzee, several species of monkey, 2 species of squirrel, and perhaps other animals) may serve as the source of human infections.

Even in the parts of Zaire in which it appears to be the most common and is best reported, monkeypox is a rare disease (331 known cases in a population of about 5 million during the 5 years 1982-1986). However, serological studies suggest that occasionally subclinical infections occur among unvaccinated as well as vaccinated

persons. There is no reason to believe that it is a new disease or that its frequency is increasing. Indeed, it appears to be disappearing from countries in western Africa, probably because of ecological changes associated with development.

## OTHER ORTHOPOXVIRUS INFECTIONS OF MAN

As well as being the natural host of variola virus and an occasional, incidental host of monkeypox virus, man is susceptible to 2 other species of *Orthopoxvirus*, each of which has a broad host range: vaccinia and cowpox. Deliberate vaccination and accidental person-to-person infection with vaccinia virus have been described in Chapter 7. The present chapter is here concerned with human infections with vaccinia and cowpox viruses acquired from animals and with camelpox.

### Vaccinia

#### General

Since vaccination was formerly practised on such a large scale and since vaccinia virus has a broad host range, it is not surprising that domestic animals were sometimes accidentally infected with the virus (Topciu et al., 1976). Human beings could, in turn, be infected from the lesions on domestic animals. Dekking (1964) found that in 36 virologically confirmed outbreaks of "cowpox" in cattle in the Netherlands, 28 were caused by cowpox virus and 8 by vaccinia virus. In the USSR, Maltseva et al. (1966) showed that each of 5 outbreaks of a pox disease affecting cattle and human beings between 1959 and 1963 was caused by vaccinia virus.

### Outbreaks of Vaccinia in Cattle and Man

In 1964 an outbreak of pox infection occurred on a dairy farm in El Salvador in which 22 persons and 450 cows were affected (Lum et al., 1967). It was detected following the admission to hospital of 2 patients with pustular nodules on the hands. All except one of the human cases occurred in milkers; the exception was a woman who washed the towels used by the milkers to clean the cows' udders. Almost all the cows in the herd were infected before the epizootic ceased. The source of the infection was a milker who had been vaccinated on 18 August, had a severe primary reaction, and returned to work on 2 September. The first primary human case occurred 9 days later, presumably via lesions on a cow. Vaccinia virus was recovered from 5 human patients and 1 cow.

*Buffalopox*

Buffalopox, due to infection of buffaloes with vaccinia virus, was a relatively common disease in India and in other countries in which buffaloes are used for milk production (Lal & Singh, 1977). Usually lesions were confined to the teats of milking buffaloes, but sometimes generalized lesions occurred and calves got lesions on the face and mouth which interfered with their ability to suck. Human infections, usually comprising small lesions on the hands or forearms of milkers, occurred in most outbreaks and acted as the principal mode of transfer of the virus from one buffalo cow to another. The vaccination of milkers was positively incriminated as the source of one outbreak in the USSR (Ganiev & Farzaliev, 1964) and all other outbreaks have occurred in situations in which the infection of the buffaloes could have originated from vaccinated human beings. The causative agent was identified as vaccinia virus in most outbreaks. Baxby & Hill (1971) categorized 1 isolate as a separate species—"buffalopox virus"—on the basis of its biological characteristics, notably a ceiling temperature of 38.5 °C compared with 41 °C for vaccinia virus and the production of smaller pocks on the chorioallantoic membrane and smaller plaques in RK 13 cells. However, analysis of the DNA of this isolate indicates that it is also a strain of vaccinia virus (K. R. Dumbell, personal communication, 1982).

It was assumed that buffalopox would cease to occur after the cessation of routine vaccination in 1979–1980, but outbreaks continue to be reported in Maharashtra State and other parts of India. Analysis of the DNA of viruses recovered from lesions in buffaloes shows that they are strains of vaccinia virus (K. R. Dumbell, personal communication, 1986). These outbreaks do not appear to have been associated with human vaccination; studies on their epidemiology are in progress as this book goes to press.

**Cowpox***History and geographical distribution*

The history of cowpox in relation to the origins of Jennerian vaccination has been described in Chapters 2 and 6. It was not until 1939 that Downie (1939a,b) clearly differentiated cowpox virus from vaccinia virus. Classical cowpox has not been described outside of Europe, but strains of cowpox virus have been recovered from rodents in Turkmenia (USSR).

*Epidemiology*

The traditional mode of infection of human beings with cowpox virus was by "inoculation" of the hands of milkers by contact with ulcers on the teats of cattle caused by cowpox virus (see Plate 29.6 A and 29.6 D). This was undoubtedly the usual

Table 29.13. Features of 16 virologically confirmed cases of infection of humans with cowpox virus in England<sup>a</sup>

<sup>b</sup> Occupations of the other patients were diverse.

mode of infection and over the years many such episodes have been reported. Human cowpox was regarded as a rare zoonosis, contracted by the direct contact of milkers with lesions on the teats of cows and resulting in an ulcer or ulcers that remained localized at the inoculation site (Downie, 1951, 1965a; Dekking, 1964).

**Plate 29.9.** Derrick Baxby (b. 1940). British authority on orthopoxviruses, with a particular interest in cowpox and the history of vaccination.

Bovine cowpox is not a common disease (Gibbs et al., 1973) and apparently never was, even in Jenner's time, and the occurrence of lesions of "spurious cowpox" on cows' teats (see below) gave rise to much confusion when such lesions were used as a source of vaccine. Ceely (1842), who provided one of the best and most detailed descriptions of cowpox in bovines, noted that: "The disease is occasionally epizootic . . . more commonly sporadic or nearly solitary. It may be seen sometimes at several contiguous farms, at other times one or two farms entirely escape its visitation. Many years may elapse before it recurs at a given farm or vicinity, although all the animals may have been changed in the meantime."

Baxby (1977a; personal communication, 1983) has pointed out that cows were directly implicated as a source of cowpox virus in only 3 out of 16 virologically confirmed cases in human beings in England between 1969 and 1981 (Table 29.13). No source of infection could be discovered for the other 13 cases. Only 4 of the cases occurred in farm workers. Other studies (review: Baxby et al., 1979) have shown that cowpox virus (defining the species according to the biological characteristics described in Chapter 2, Table 2.3) has caused sporadic infections in domestic cats, large felines, elephants, okapis and a rhinoceros (Table 29.14), none of these infections

Analysis as for Fig. 29.1. Number of attributes = 70. (Data from Mackett, 1981.)

having originated from contact with cases of bovine or human cowpox. The validity of the species diagnosis is supported by analyses of the DNA obtained from several of these isolates (Fig. 29.4). All could be clearly differentiated from vaccinia and variola DNA. The dissimilarities between different strains of cowpox DNA relate in a general way to their geographical origins, and strains from unusual hosts (elephants and large felines) clearly have cowpox virus DNA.

Man, cows and the other animals listed in Table 29.14 are probably all incidental hosts of cowpox virus, of no importance as far as its perpetuation in nature is concerned. The recovery of cowpox virus from wild rodents in Turkmenia (Ladnyj et al., 1975; Marennikova et al., 1978b; Plate 29.10) and the demonstration that a substantial number of them were serologically positive (Table 29.15) suggests that susliks and gerbils might be natural reservoir hosts of cowpox virus in

Turkmenia. These animals do not occur in the United Kingdom, but Kaplan et al. (1980), in a study of virus infections in small British field rodents, demonstrated orthopoxvirus antibodies in wild voles; these could be due to cowpox virus. It is not unreasonable to suppose that cowpox virus, which has a wide host range, produces enzootic infections in a variety of rodents, from which it is occasionally transferred to other animals: cows, cats, zoo animals (possibly via domestic rats used as feed, as in the Moscow Zoo outbreak; Marennikova & Shelukhina, 1976) and sometimes man (Baxby, 1977a, 1982b). In turn, cows, cats and sometimes zoo animals (Marennikova et al., 1977) could serve as the source of infection for humans.

#### *Differential diagnosis of lesions on cows' teats*

Jenner recognized that not all ulcers on the teats of dairy cows were caused by "variola"

Table 29.15. Evidence of cowpox virus infection in white rats in Moscow and in wild rodents in Turkmenia<sup>a</sup>

vaccinae", so that material taken from such lesions sometimes lacked the capacity to protect humans against smallpox; he termed such lesions "spurious cowpox" (Jenner, 1799). In addition to cowpox and vaccinia virus, 2 other viruses can cause ulcers on the teats of cows (Gibbs et al., 1970; Baxby, 1981). These are bovine herpes mammillitis virus and pseudocowpox virus (Plate 29.6 B). Both are enzootic diseases of bovines, and are much more common than cowpox virus infections in dairy herds. Pseudocowpox virus is transmissible to man, to produce milker's nodules (see below).

#### *Clinical features of cowpox in man*

Downie (1965a) has described the lesions found in humans infected with cowpox virus (Plate 29.6 D) as follows. One or more lesions usually appear on the hands—the thumbs, the first interdigital cleft and the forefinger being especially liable to attack. Scratches or abrasions of the skin may determine the localization of the lesions elsewhere on the hands, forearms or face. The lesions resemble those of primary vaccination, passing through the stages of vesicle and pustule before a scab forms. Local oedema is usually more pronounced than in vaccination and there is lymphangitis, lymphadenitis and often fever for a few days. Baxby (1977a) noted that cowpox in children was occasionally rather severe. However, although multiple primary lesions sometimes occur, a generalized rash has not been reported, but one case of post-cowpox encephalitis has been described (Verlinde, 1951).

### Camelpox

Camelpox is a common disease of dromedary camels. The original report identifying camelpox virus as an orthopoxvirus (Baxby, 1972) caused some concern to those involved in the global smallpox eradication campaign since it was entitled "Smallpox-like viruses from camels in Iran". However, subsequent investigations (see Chapter 2) showed that it was caused by a distinct species of *Orthopoxvirus* that has a narrow host range. Among camels, skin lesions occur mainly on the head, neck and forelegs, or all over the body. Young animals, in particular, may suffer a severe disease which is sometimes fatal (Plate 29.11). Camelpox is enzootic in Somalia (Ježek et al.,

1983) and in most other areas in which camels are common (Egypt, India, the Islamic Republic of Iran, Iraq, Kenya and the USSR) but not among feral camels in Australia.

Although there were occasional reports in the older literature that camel drivers could contract local lesions on the hands and arms from contact with affected animals, the experience during the global smallpox eradication programme, especially in Somalia, suggested that human camelpox rarely if ever occurred. Kříž (1982) described a possible case in a 40-year-old unvaccinated Somali man who was a member of a nomadic group among whose camels there was a severe epizootic of camelpox. There were 3 lesions on the left arm and 1 on the right, which went through vesicular and pustular stages before scabbing. It was not possible to obtain lesion material for laboratory confirmation, but the serum from this patient gave a positive orthopoxvirus HI test. A survey among 286 camel herdsmen in the area, only one-third of whom had been vaccinated, revealed only 2 other cases of skin lesions, both diagnosed as tropical ulcers. A subsequent survey of another 179 herdsmen handling affected camels, 12% of whom had been vaccinated, revealed few skin eruptions, none of which yielded a poxvirus (Ježek et al., 1983). Out of a total of 335 specimens taken from the skin lesions of persons who might have come into contact with diseased camels, none was positive for poxvirus particles, and inquiries among some 20 000 persons at risk yielded only 1 possible case of human camelpox, that reported by Kříž (1982).

### PARAPOXVIRUS INFECTIONS

A number of domestic animals—sheep, goats, cattle, and camels—sustain infections with different strains or species of the genus *Parapoxvirus*. The lesions in each species of animal usually take the form either of scattered papules and nodules in the skin or of a papular stomatitis, with lesions on the lips and gums ("scabby mouth" of sheep; bovine papular stomatitis). One strain of parapoxvirus is spread among cows and produces ulcerative lesions on the teats (Plate 29.6 B), which are called pseudocowpox and constitute one of the forms of the "spurious cowpox" of Jenner (Gibbs & Osborne, 1974). Calves sucking from dams with pseudocowpox usually get lesions on the mouth and

**Plate 29.12.** **A:** Virions of the parapoxvirus of pseudocowpox, which produces lesions of milker's nodules in humans. **B:** Virion at higher magnification, showing the regular spiral structure of the tubule of the outer coat, which is characteristic of the genus *Parapoxvirus*.

lips. Bovine papular stomatitis is caused by a different species of parapoxvirus and is found more commonly in beef than in dairy cattle (Tripathy et al., 1981). Five out of 57 cases of "camelpox" in Somalia that were investigated virologically in 1978–1979 were caused by a parapoxvirus (J. H. Nakano, personal communication, 1986).

Humans can be infected accidentally with these parapoxviruses through abrasions of the skin. The disease acquired from sheep or goats is termed orf (review: Johannessen et al., 1975); that acquired by milkers from the ulcers on the teats of cattle is called milker's nodules. The lesions in cattle and sheep often ulcerate; milker's nodules in humans are usually small indolent papules (Plate 29.6 E). Human orf is associated with umbilicated proliferative lesions that often ulcerate before healing (Plate 29.6 F).

All parapoxviruses have an identical morphology, which is quite distinctive (Plate 29.12), the virions being smaller than those of the orthopoxviruses and having a regular surface structure.

Parapoxvirus infections are of some importance in the consideration of smallpox for two rather trivial reasons: the lesions on cows' teats constituted an early source of confusion with genuine cowpox, and the particles found in scrapings of human lesions reported by electron microscopists simply as "poxvirus particles" might unnecessarily alarm public health authorities.

### MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a specifically human skin disease caused by a poxvirus which has not yet been cultivated or transmitted to laboratory animals (review: Postlethwaite, 1970). The lesions are pearly, flesh-coloured, raised, firm, umbilicated skin nodules, 2–5 mm in diameter, which may appear anywhere on the body except the palms and soles. The nodules are painless and at the top of each there is often an opening through which a small white core can be seen. There are no constitutional disturbances. The le-

sions may persist for months or even a few years before resolving spontaneously.

Molluscum contagiosum has a world-wide distribution. In some places—e.g., Papua New Guinea (Sturt et al., 1971) and Zaire—it is very common in children. It may occur sporadically or in small epidemics. Direct or indirect contagion appears to be the mode of spread and in western countries public baths and swimming-pools may be implicated. Among young adults it may be a sexually transmitted disease (Brown et al., 1981).

In negatively stained preparations the virions are morphologically very like those of vaccinia virus, although Nakano (1985) noted that the surface tubules were more prominent. However, since the lesions are so distinctive, and since the virus cannot be cultivated, molluscum contagiosum was not regarded as a serious source of confusion in the global smallpox eradication campaign.

### TANAPOX VIRUS INFECTIONS

Tanapox was first observed as an acute febrile illness, associated with localized nodular skin lesions and caused by a poxvirus, which occurred in epidemics in 1957 and 1962 among people living in the flood plain of the Tana river in Kenya (Downie et al., 1971). Serological studies (Manson-Bahr & Downie, 1973) showed that it was endemic in this area, and subsequently many cases were seen during surveillance for monkeypox in Zaire in 1977–1984 (Ježek et al., 1985). The same virus (Downie & España, 1972) gave rise to epizootic infection in rhesus monkeys in 3 primate centres in the USA in 1966; in each of these outbreaks some of the animal handlers were infected, apparently through skin abrasions (Nakano, 1978).

Ježek et al. (1985) have published a detailed analysis of the clinical and epidemiological features of tanapox as seen in 264 cases in Zaire in which the diagnosis was confirmed by electron microscopy. The incubation period in natural human cases is unknown, but in a person infected by the intradermal inoculation of about  $10^4$  infectious particles (as assayed in tissue culture), erythema and central thickening appeared by the 4th day (Downie et al., 1971). Most patients have a mild pre-eruptive fever, sometimes accompanied by severe headache and backache and often with itching at the site of the eventual skin lesion.

The appearance and evolution of the characteristic skin lesions are illustrated in Plate 29.7. Initially there is a small nodule, without the central abrasion that is often seen with an insect bite. The nodule soon becomes papular and gradually enlarges to reach a maximum diameter of about 15 mm by the end of the second week. It is surrounded by an oedematous zone and a large erythematous areola. The draining lymph nodes are enlarged and tender from about the 5th day after the appearance of the skin lesion, which may remain nodular but usually ulcerates during the third week and then gradually heals within 5–6 weeks, leaving a scar. In Kenya, Downie et al. (1971) noted that the lesions were almost always solitary and on the face, neck, upper arm and trunk. In Zaire, however, Ježek et al. (1985) noted that 22% of patients had multiple lesions—usually 2 but sometimes 3 or more, the maximum number seen on one patient being 10. Multiple lesions were often close together and usually evolved simultaneously, although they differed in size. In Zaire the distribution of lesions was different from that seen in Kenya, 72% being on the lower limbs, 17% on the upper limbs, 7% on the trunk and 5% on the head.

Especially if there were multiple lesions, a case of tanapox could initially be mistaken for human monkeypox (or in former times smallpox), perhaps modified because of vaccination, but the slow evolution and lack of pustulation clearly differentiate tanapox from any of the orthopoxvirus infections. The clinical diagnosis can be confirmed by the demonstration with the electron microscope of poxviruses which have a characteristic envelope (Plate 29.13) and fail to grow on the chorioallantoic membrane (Nakano, 1985).

Some strains of tanapox virus grow in cultures of monkey or human cells, producing focal lesions characterized by intense granularity followed by rounding up of the cells. Monkeys, but no other laboratory animals, are susceptible to experimental infection.

Human tanapox has been recognized in Kenya and Zaire, but probably occurs much more widely throughout tropical Africa. In Kenya, Downie et al. (1971) noted that epidemics in 1957 and 1963 were associated with periods of extensive flooding. In Zaire, cases occurred throughout the year but mainly in the period between November and

BY COURTESY OF J. H. NAKANO

**Plate 29.13.** Virions of tanapox virus, as seen in negatively stained scrapings from a lesion. Most virions appear to have an envelope.

March (Ježek et al., 1985). The majority of cases seen in Zaire were found in the township of Lisala, among persons living within 300 metres of the Zaire river. Both sexes and all age groups were affected, and cases occurred much more frequently among persons who worked or played close to the river than among those engaged in hunting or working as plantation farmers. Although clusters of cases occurred both temporally and spatially, there was no indication that person-to-person spread occurred. Tanapox appears to be a zoonosis, but neither the reservoir host nor the mode of transmission from wild animals to man is known. Manson-Bahr & Downie (1973) suggested that tanapox virus may be transferred from monkeys or some other reservoir host to man by biting arthropods, possibly acting as mechanical vectors. Infection by mechanical transmission has been described among animal attendants (McNulty et al., 1968).

### GENERAL COMMENT

Man is susceptible to a range of poxvirus infections, but only two of these, smallpox

and human monkeypox, regularly produce an acute systemic infection with a generalized rash. Human monkeypox can be distinguished from smallpox only by the cultivation of the virus or the performance of a virus-specific serological test with convalescent serum, but the epidemiology of the two infections is quite different. Monkeypox was the only poxvirus infection other than smallpox seen during the eradication programme that gave rise to serious concern. However, the studies in Zaire described in this chapter provide good evidence that it is a rare zoonosis which cannot be sustained indefinitely by serial transmission in man.

Because vaccination can greatly modify the response of humans to either variola or monkeypox virus, so that if skin lesions do occur, they are very few or perhaps only a solitary one develops, other poxvirus infections sometimes cause problems in the differential diagnosis of smallpox or monkeypox, especially because electron microscopic examination of lesion material might reveal poxvirus particles.

The diagnosis of cowpox and vaccinia infections depends on the cultivation of the virus on the chorioallantoic membrane; that of tanapox on the clinical picture, the appearance of the virion in the electron microscope and its failure to grow on the chorioallantoic membrane. The lack of systemic symptoms and the characteristic chronic nodular skin lesions distinguish molluscum contagiosum from all other poxvirus diseases. The viruses of orf and milker's nodules can readily be distinguished by the characteristic morphology of the virion, as well as by serological tests.

When they were first studied in the laboratory, camelpox virus (Baxby, 1972) and taterapox virus (Lourie et al., 1975) were regarded with considerable suspicion because the pocks they produced on the chorioallantoic membrane very closely resembled those produced by variola virus. It is possible that similar causes of concern may arise, perhaps with orthopoxviruses of wild animals that have yet to be discovered. Comparison of their DNA with that of variola and monkeypox viruses should allow the proper categorization of any such isolates.

### INTRODUCTION

The eradication of smallpox was defined by successive WHO expert groups (WHO Scientific Group on Smallpox Eradication, 1968; WHO Expert Committee on Smallpox Eradication, 1972) as "the elimination of clinical illness caused by variola virus". An important corollary of this definition was that it did not involve the extinction of variola virus, as some experts had urged. The procedures for the certification of smallpox eradication described in Chapter 24 were therefore designed to ensure that no human cases had occurred in the countries concerned for at least 2 years—i.e., that the human-to-human chains of transmission of smallpox had been interrupted. Careful follow-up of

rumours of suspected smallpox by national authorities and by WHO, described in Chapter 28, has failed to confirm a single case of smallpox in a field situation since the last case was recognized in Somalia in October 1977, although there were 2 laboratory-associated cases in Birmingham, England, in August–September 1978. The correctness of the conclusions that the Global Commission for the Certification of Smallpox Eradication arrived at in its deliberations in December 1979 (World Health Organization, 1980) has been borne out by 10 additional years of freedom from the disease.

As the expert groups which defined eradication recognized, the absence of cases of smallpox is not synonymous with the extinction of variola virus, and if the virus is

not extinct it is possible that further cases of smallpox could occur. This chapter is concerned with the known and hypothetical ways in which variola virus could be preserved and enter again into chains of human-to-human transmission. By far the most important, because it would be the most difficult to eliminate or circumvent, would be the continuing transmission of the virus in some wildlife reservoir or reservoirs. Indeed, such a situation would have made the permanent global eradication of smallpox an impossibility. This was therefore a matter that greatly exercised the staff of the WHO Smallpox Eradication unit from the outset of the global eradication programme (see Chapters 10 and 29). The lack of evidence of infection of humans from an animal host in Europe, North America and Australia, in which the disease no longer occurred, did not exclude this possibility for parts of Africa and Asia in which smallpox was still endemic until the 1970s. Although there was no documented evidence that this had taken place, it was conceivable that infection of man from an animal source might have occurred in the past without having been detected, as indeed proved to be the case with human monkeypox. Because of the reported isolations in laboratories in Bilthoven (Netherlands) and Moscow (USSR) of variola-like viruses ("whitepox" viruses) from animal tissues (see later in this chapter), investigation of this possibility remained a major concern of virologists involved in research associated with the eradication programme throughout the 1970s and into the early 1980s.

Material stored by variolators was another potential source for the recurrence of cases of smallpox which concerned the WHO Secretariat and members of the Global Commission, especially in countries such as Afghanistan in which low temperatures prevailed for much of the year. However, the most obvious source of virus that might cause human infection at some time in the future consists of laboratory stocks of variola virus, from which, indeed, the last known outbreak in the world originated (see Chapter 23). These could be stocks of virus known by WHO to be held in microbiologically secure laboratories, or they could be specimens in the deep-freeze storage facilities of any laboratory that had ever worked with the virus. Finally, stocks of virus may be held secretly, for possible use in microbiological warfare.

Other hypothetical sources of smallpox

could be from virus released by reactivation in a human subject who had had the infection, or release of viable virus long preserved in scabs, on old clothes, or even in coffins. For the sake of completeness the possibility that another species of *Orthopoxvirus* might be "transformed" into variola virus (already discussed in Chapter 2) needs to be briefly reconsidered here, as a possible source for the return of smallpox.

## IS THERE AN ANIMAL RESERVOIR OF VARIOLA VIRUS?

The presence of an animal reservoir of variola virus is in theory the most important potential source for a return of smallpox. In discussing the origin of variola virus in Chapter 2, we suggested that conditions suitable for its perpetuation as a specifically human pathogen have existed for a few thousand years at the most. Variola virus was therefore probably derived from some closely related orthopoxvirus that survived in nature by circulation in an animal that occurred in large numbers at the time of early man and had a much shorter life-span. In this chapter two possibilities will be discussed: that there is an animal reservoir of variola virus as we know it, or that some other animal orthopoxvirus could be "transformed" into variola virus by a few mutational steps or perhaps by chance recombination with another animal orthopoxvirus. The great importance of this question, from the point of view of smallpox eradication, can be illustrated by reconsidering briefly the history of the first deliberate attempt to eradicate a human disease, yellow fever, which has already been mentioned in another context in Chapter 9.

### The Example of Yellow Fever

In 1915 the International Health Commission of the newly established Rockefeller Foundation agreed to help with the global eradication of yellow fever, an undertaking that General W. C. Gorgas, Surgeon-General of the United States Army and the hero of disease control during the construction of the Panama Canal, considered eminently feasible. Yellow fever was regarded as an urban disease, and its global eradication was based on a simple epidemiological concept:

"...that the disease could be acquired only through the bite of an *A. aegypti* mosquito that had become infected by feeding on a human being sick with yellow fever; that there were certain endemic centers of the disease that served as seedbeds; that these foci of infection were few in number, and that if they were destroyed, yellow fever would disappear forever." (Warren, 1951.)

It is a matter of history that this concept was too simple. As early as 1907 Franco et al. (1911) had recognized the existence in Colombia of another epidemiological situation—the contracting of yellow fever in the forest, rather than in urban areas. Another outbreak of yellow fever occurred in the same locality in 1916, but since *Aedes aegypti* could not be found there, it was assumed by the Gorgas Commission that the diagnosis was erroneous (Gorgas, 1917). Eventually Soper (1935, 1936) drew attention again to the paper of Franco et al. and described what he called "jungle yellow fever", which he postulated could be due to maintenance of the virus in another vertebrate host or perhaps long persistence in an invertebrate vector. At about the same time surveys of forest monkeys of many species in both Africa and South America revealed the presence of neutralizing antibodies in their sera. With the discovery of a vertebrate reservoir other than man, it was clear that the global eradication of yellow fever was impossible, although urban yellow fever could be eliminated by ridding towns and cities of *Aedes aegypti*.

The significance of the yellow fever experience was not lost on those who contemplated the global eradication of smallpox and investigations into the possibility that there might be an animal reservoir of variola virus in Africa or Asia were initiated soon after the Intensified Smallpox Eradication Programme was launched (see Chapter 10).

### Smallpox in Apes and Monkeys

Experimental observations with variola virus had demonstrated that, unlike vaccinia and cowpox viruses, both of which have a wide host range, few laboratory animals could be infected with variola virus, except under unusual conditions (see Chapter 2). However, it had been demonstrated during the latter part of the 19th century that monkeys (probably *Macaca mulatta*) could be infected with variola virus (Zuelzer, 1874; Copeman, 1894), and later studies (Hahon, 1961) showed that many species of monkeys and apes were susceptible. Noble (1970) found that 3 species of New World monkeys that he tested were insusceptible to variola minor virus, although they reacted serologically but without symptoms to experimental infection with variola major virus.

#### Reported infections of primates in nature

Arita & Henderson (1968) reviewed the published accounts of supposed smallpox in primates as well as other naturally occurring epidemics of "pox" infections among monkey populations. Only 8 such episodes are known and only 4 of these occurred during the present century (Table 30.1). In only 2 instances was laboratory confirmation available; in each of these there had been close association between the primate concerned and cases of human smallpox.

"Smallpox" infection in a monkey population in the forests of southern Brazil was reported by Bleyer (1922), who noted that carcasses of *Myrcetes seniculus* and *Cebus capucinus* were found under the trees, the dead animals having fallen from the tree-tops. Sick as well as dead monkeys were covered with numerous pustules like those seen in human smallpox and the mortality was extremely

<sup>b</sup> Serological and epidemiological evidence suggesting infection with variola virus.

high in certain districts. Anderson (1861) reported that a "smallpox" outbreak observed in 1841 in monkeys was followed by a smallpox outbreak in a human population in Panama. Two monkeys that he examined were covered with "perfectly formed" pustules. Schmidt (1870) mentioned 3 other episodes, 2 in France and 1 in Trinidad.

An outbreak of a vesiculo-pustular disease was observed by M. A. Rahman (quoted by Arita & Henderson, 1968) in rhesus monkeys in Bengal, India, in 1936. Many deaths were observed among monkeys which lived in mango groves near the town and visited the town frequently in search of food and water. The sick monkeys were quiet and lethargic and had pustular lesions, particularly on the face, palms and soles. When they died they fell from the trees and roof tops, and the carcasses were disposed of without any particular precautions being taken. Despite the poor vaccinal immunity status of the population, no human pox-like illnesses were observed.

All these episodes must be regarded with caution so far as their significance as evidence of an animal reservoir of variola virus is concerned. They may have been instances of the infection of primates from human cases of smallpox or they may have not been due to variola virus or indeed to any kind of poxvirus. However, 2 episodes have been well documented which demonstrate that primates in close contact with smallpox-infected humans may have become infected with variola virus. Gispén (1949) observed 2 orang-utans in the Jakarta Zoo which contracted a pox infection at the time of a smallpox epidemic in the area. Both animals were in the same cage and demonstrated typical lesions on the face, hands, and soles of the feet; Bras (1952a) performed an autopsy on the one that died (Plate 30.1). Variola virus was isolated on the chorioallantoic membrane of the chick embryo from specimens taken from both affected animals. Other monkeys in the zoo, none of which had been previously vaccinated, remained unaffected. The other episode occurred in India, where Mack & Noble (1970) recorded an unusual situation in which 1 or possibly 2 performing monkeys (*Macaca mulatta*) appear to have been infected with variola virus by intimate household contact with human cases of smallpox.

Throughout the global smallpox eradication campaign attempts were made to identify the source of infection in all outbreaks,

G. BRAS

**Plate 30.1.** Orang-utan (*Pongo pygmaeus*) in the Jakarta Zoo, which was infected during the 1949 epidemic of smallpox and died.

and as the incidence of smallpox fell to low levels in each endemic country, this became a matter of high priority, so that chains of transmission could be traced. Thousands of such outbreaks in Africa and south-eastern Asia were investigated by skilled epidemiologists. In the vast majority, infection could be traced to a case of smallpox. Very rarely fomites (e.g., laundry items or burial shrouds) were implicated. In a few instances it was not possible to determine the source of the outbreaks. Some of them may have been due to infection acquired from mild unrecognized cases, or the source remained undetected through faulty or incomplete investigation. But the possibility of infection from an animal source was always present in the minds of epidemiologists in the rare instances in which no human source could be clearly identified. Never during the global smallpox eradication campaign could smallpox be traced back to an animal source. Finally, although monkeys are common in many of the countries of Africa and Asia in which smallpox was once endemic, sometimes living in close contact with man or

captured by hunters, no case of smallpox has been found in any of these countries since eradication.

### *Experimental transmission of smallpox between primates*

More significant than isolated examples of smallpox in monkeys or the infection of animals by inoculation are 2 sets of observations on the natural transmission of variola virus from one primate to another. Noble & Rich (1969) showed that serial infection could be maintained for as many as 6 successive passages in *Macaca irus* (cynomolgus) monkeys placed in contact with other monkeys during the period of rash, but transmission then failed (Fig. 30.1). Among chimpanzees, Kalter et al. (1979) observed that 2 animals situated in cages near a chimpanzee experimentally inoculated with variola virus contracted smallpox, one suffering a severe illness. One other animal in the group escaped infection. Clearly, primates of several species are susceptible to variola virus, get a rash when infected, and can transmit the disease to other primates in contact with them. However, in *Macaca irus*, the only primate in which adequate studies were conducted, the infection persisted with some difficulty and then died out.

As was discussed in Chapter 2, smallpox could not be maintained in isolated human

populations numbering under 200 000. Unless smallpox in non-human primates produced a situation in which recurrent infectivity could occur years after the primary infection, it is likely that populations of any particular species of monkey would be too small to maintain the disease. This is certainly true of chimpanzees and orang-utans, in which infection with variola virus causes a severe disease not unlike smallpox in man.

### Monkeypox

It had been known since 1958 that monkeys in laboratory colonies occasionally suffered epizootics due to another orthopoxvirus—monkeypox virus (Magnus et al., 1959; see Chapter 29). Known outbreaks of monkeypox were reviewed by Arita & Henderson (1968), and early in 1969 the WHO Smallpox Eradication unit convened an Informal Group on Monkeypox and Related Viruses (see Chapter 29) to advise it on matters relating to the problem of an animal reservoir of variola virus. The following year one of the members of the Informal Group (Dr Svetlana Marennikova) recognized that the virus recovered from a suspected case of smallpox that had occurred in Zaire 2 years after the last outbreak of smallpox in the area (Ladnyj et al., 1972) was indeed monkeypox virus (Marennikova et al.,

Fig. 30.1. Five successive contact infections of *Macaca irus philippinensis* before failure in transmission. The first monkey was infected by intranasal inoculation and after 7 days (indicated in bar) developed many lesions, from which variola virus was recovered (first '+' symbol) and subsequently showed serological conversion (second '+' symbol). The second monkey was placed in the same cage 3 days after the inoculation and developed 54 lesions 11 days after exposure; it was then placed in contact with the third monkey, and so on. The penultimate monkey in the series developed 13 lesions, but virus was not recovered from the crusts, although antibodies developed. The last monkey failed to develop lesions or convert serologically. (Based on Noble & Rich, 1969.)

1972b). Subsequently, human monkeypox has come to be recognized as a rare zoonosis apparently confined to villages in tropical rain forests in central and western Africa (see Chapter 29). The significance of human monkeypox in the present context lies in observations made in the course of ecological surveys in Zaire designed to elucidate the natural history of monkeypox virus. These resulted in a series of reports on what came to be called "wild whitepox" and ultimately "whitepox" viruses.

### "Whitepox" Virus Isolations

Three sets of isolations of "whitepox" viruses have been made which are best dealt with separately and chronologically. The first set ("Netherlands isolates") comprises 2 strains, designated 64-7255 and 64-7275, apparently recovered from normal cynomolgus monkey kidney cell cultures at the National Institute of Public Health at Bilthoven (Gispen & Kapsenberg, 1966; Gispen & Brand-Saathof, 1972). The second

### White Pock Mutants, "Whitepox" Viruses and White Clones (Variants) of Monkeypox Virus

The appearance of pocks produced on the chorioallantoic membrane by different species of *Orthopoxvirus* varies from bright red (cowpox virus), through a greyish ulcerated appearance with a haemorrhagic centre (monkeypox virus and some strains of vaccinia virus including rabbitpox virus) to a dense white pock with no sign of ulceration (variola virus, some strains of vaccinia virus and camelpox virus). All viruses that produce haemorrhagic pocks also yield a small proportion of non-haemorrhagic pocks; these are the "white pock mutants" of cowpox, rabbitpox, neurovaccinia or monkeypox virus, which have been used for genetic studies of orthopoxviruses.

In 1966 Gispen & Kapsenberg reported the recovery of orthopoxviruses from apparently normal cynomolgus monkey kidney cells used for viral diagnostic work in the National Institute of Public Health, Bilthoven. One of them was vaccinia virus; the other 3 were regarded as monkeypox virus. However, when studying these "monkeypox" virus isolates, Marennikova et al. (1971) showed that one of them resembled variola virus and was clearly distinguishable from monkeypox virus. Gispen & Brand-Saathof (1972) confirmed this result with 2 of the 3 "monkeypox" virus isolates and in the same paper observed that a white pock mutant that they recovered from monkeypox virus resembled the parental virus in most properties and was clearly distinguishable from variola virus. To discriminate between them, the variola-virus-like strains were called "wild white" poxvirus, or "whitepox" virus.

Between 1971 and 1975 Marennikova and her colleagues at the Moscow Research Institute for Viral Preparations reported that they had recovered white-pock-producing orthopoxviruses from the tissues of 4 species of animals shot in Zaire (chimpanzee, monkey, sun squirrel and multimammate rat). All isolates resembled Gispen's "wild white" poxvirus (and thus variola virus) in all the biological properties that they could test. For purposes of reference, the term "whitepox" virus was used to include all six of these viruses (Arita & Henderson, 1976).

In 1978-1979 Marennikova and her colleagues reported that they had obtained "whitepox" by inoculating monkeypox virus on the chorioallantoic membrane and in hamsters. They called these isolates "stable white clones" or "white variants" of monkeypox virus.

In this way two terms came to be used by virologists associated with the smallpox eradication programme:

- (1) White pock mutants—of rabbitpox, cowpox and monkeypox viruses; and
- (2) "Whitepox" viruses—from normal cynomolgus monkey kidney cells, from apparently normal wild animals shot in Zaire, or found as "stable white clones" or "white variants" of monkeypox virus.

set ("Zaire isolates") comprises 4 strains of virus reported by workers at the Moscow Research Institute for Viral Preparations to have been recovered from the tissues of 4 different species of wild animal captured in Zaire between 1971 and 1975 (Table 30.2). The third set ("white clones") comprises several isolates made from preparations of monkeypox virus maintained at the Moscow

Research Institute for Viral Preparations (Marennikova & Shelukhina, 1978; Marennikova et al., 1979).

#### *Netherlands isolates*

During 1964 and 1965 4 orthopoxvirus isolations were made from cynomolgus monkey kidney cells that were being used for the

### Laboratory Contamination with Viruses

Bacteriologists are accustomed to the idea that unwanted organisms may occasionally find their way into culture media and multiply there. Indeed, the discovery of penicillin resulted from one such episode (Fleming, 1929). Similar accidents may occur with viruses, especially if manipulations are of the kind that produce aerosols. Only a few cases of the contamination of cultures have been reported (e.g., Andrewes et al., 1944). Another kind of environmental contamination is the accidental infection of laboratory workers (see, for example, Pike, 1979; Wedum et al., 1972), which is an indicator of the possibility of infection of laboratory cultures.

H. Mahnel (personal communication, 1984), concerned about the occasional occurrence of vaccinia virus plaques on "uninfected" cell monolayers, carried out tests with vaccinia and monkeypox viruses under conditions simulating those in the laboratory. The infectivity of tissue culture fluid dried on coverslips and stored in Petri dishes in the shade in the laboratory (temperature 20–23 °C) dropped from  $10^{5.8}$  plaque-forming units per ml to  $10^{2.8}$  plaque-forming units per ml in 12 days, but the dried material did not completely lose infectivity until the 6th week. He believes that the principal source of laboratory contamination of cultured cells arises from droplets of infected fluid drying on bench tops and in the dust of the laboratory.

Although the risk of cross-infection can be reduced by good microbiological technique, there is an ever-present possibility of the contamination of tissue cultures or eggs. Almost every laboratory manipulation is associated with some risk of producing aerosol particles that could contain virus. Dimmick et al. (1973) have drawn up a table listing the "spray factors" of various laboratory operations and accidents. Assuming that a viral suspension contains  $10^7$  pock-forming units per ml, it is possible to calculate the number of infectious aerosol particles released as a result of normal laboratory operations or minor accidents.

<i>Operation</i>	<i>Spray factor</i>	<i>Virions per m<sup>3</sup> of working area</i>
Blender opened 5 minutes after stop	$10^{-5.3}/\text{min}$	50
Pipetting, minimal bubbling	$10^{-6.3}/\text{min}$	5
Intranasal inoculation of mice	$10^{-7.3}/\text{min}$	0.5
Drop spilled from a height of 100 cm	$10^{-6.3}$	5
Removal of plug from test tube	$10^{-8.5}$	0.03

The only certain way of avoiding cross-infection with poxviruses is to use only one isolate at a time, within a glovebox facility or a biocontainment hood, and thoroughly sterilize the working area before handling another strain of virus.

Without special markers and laborious experiments, it was very difficult to "prove" that laboratory contamination had occurred, as Dumbell & Kapsenberg (1982) were able to do, but every experienced laboratory scientist who has worked with poxviruses can recall instances for which he or she believed that contamination was the most likely cause of an unexpected result.

isolation of viruses from human material in the diagnostic laboratory at the National Institute of Public Health, Bilthoven (Gispén & Kapsenberg, 1966). One strain (64-9411) was eventually diagnosed as monkeypox virus (see Chapter 29) and one strain (65-3993) was vaccinia virus, recovered together with herpes simplex virus from vesicle fluid (J. G. Kapsenberg, personal communication, 1981). The other 2 strains (64-7255 and 64-7275) were first regarded as monkeypox virus (Gispén & Kapsenberg, 1966); subsequently Marennikova et al. (1971) reported that strain 64-7275 differed from monkeypox virus in a number of biological characteristics but could not be differentiated from variola virus. This finding was confirmed by Gispén & Brand-Saathof (1972), who later showed that these 2 strains differed from monkeypox virus and resembled variola virus in tests for virus-specific antigens (Gispén & Brand-Saathof, 1974). Subsequently Esposito et al. (1978) and Dumbell & Archard (1980) demonstrated that the DNA electropherograms and restriction endonuclease maps of these 2 isolates, while differing slightly from those of some other strains of variola virus, identified them unequivocally as members of the variola virus species.

Although in a comment at the International Symposium on Smallpox Vaccine, Bilthoven, in 1972 Gispén (1973) stated, correctly, that "there was no known possible contact of these animals [from which the kidney cell cultures infected with whitepox virus had been derived; our italics] with pox viruses", it subsequently transpired that on 2 occasions in September 1964, material from smallpox patients from Vellore, India, had been handled in the diagnostic laboratory in which the cynomolgus kidney cells were being used. Skilful detective work by Dr Kapsenberg identified the passage transfer of cell cultures during which viral contamination could have occurred; there was a temporal coincidence with manipulation of the cynomolgus cells in question and cells infected with material from the smallpox cases. That laboratory contamination was the explanation was demonstrated with a high degree of confidence by the fact that the biological properties and restriction endonuclease electropherograms of strains 64-7255 and 64-7275 were identical with those of 1 of the 2 variola viruses isolated from the Vellore cases, which were slightly different from those of most

other strains of variola virus (Dumbell & Kapsenberg, 1982).

### *Zaire isolates*

Five strains of poxvirus were recovered from the kidneys of wild animals captured in Zaire and processed in the Moscow Research Institute for Viral Preparations. Four were identified as "whitepox" viruses (Table 30.2), and the fifth (MK-10-73) as vaccinia virus.

Pocks were always scanty on the membranes on which they were first observed. All subsequent investigations, including detailed DNA mapping carried out independently in 2 laboratories (St Mary's Hospital, London, England, and the Centers for Disease Control, Atlanta, USA), have confirmed that the 4 strains of "whitepox" virus are indistinguishable from variola virus.

*A priori* it is difficult to believe that a virus which has such a narrow host range as variola virus should be recovered from the tissues of 2 species of healthy rodents that are common in and near tropical forest villages in Central Africa, the rat *Mastomys natalensis* (syn. *couba*) and the sun squirrel *Heliosciurus rufobrachium*. This view is reinforced by the observation that variola virus and "whitepox" virus strain RZ-38-75, said to have been recovered from *Mastomys natalensis*, multiplied very poorly after intraperitoneal inoculation in that animal (T. Kitamura, personal communication, 1978).

Since the Moscow Research Institute for Viral Preparations functioned as one of the two WHO collaborating centres that carried out laboratory diagnosis of smallpox for the Intensified Smallpox Eradication Programme (see Chapter 10), specimens of variola virus were constantly being handled in the laboratories in which the "whitepox" virus isolates were made. The universal experience of laboratories which have handled orthopoxviruses, including the experience of the National Institute of Public Health in Bilthoven, just described, attests to the difficulty of avoiding occasional cases of laboratory contamination.

Two features caution against too ready an acceptance of this explanation for all the Moscow "whitepox" virus isolates: the positive orthopoxvirus antibody titres found in 3 of the 4 animals whose tissues apparently contained virus, and the reported reisolation of virus from part of the stored kidney of Chimp 9 (from a chimpanzee) and from a

**Plate 30.2.** Farida Huq (b. 1942) undertook graduate studies with Dr K.R. Dumbell in London before assuming responsibility for the smallpox laboratory in Dhaka, Bangladesh. Besides carrying out diagnostic work she studied the viability of variola virus in scabs under tropical conditions.

ground-up suspension of kidney tissue of RZ-38-75 (from a sun squirrel). However, investigations of the ecology of monkeypox in Zaire, reported in detail in Chapter 29, suggest that there may be several orthopoxviruses circulating among wild animals in the forests of Zaire; the antibody results signify prior infection with an orthopoxvirus, not necessarily variola virus or even monkeypox virus. Reisolation is the standard procedure for confirming the validity of suspicious isolates, but to be acceptable it must be carried out with material that had not been processed in the laboratory at the time the first isolation was made. This situation did not apply to the material from *Heliosciurus*, but it did apply to the kidney of the chimpanzee (S. S. Marennikova, personal communication, 1983), a species which is known to be susceptible to infection with variola virus (Kalter et al., 1979). However, Chimp 9 was one of the two "whitepox" viruses tested by Dumbell & Huq (1986), who showed that it resembled Asian rather than African strains of variola virus in its biological characteristics (see below).

The number of strains of variola virus whose DNAs have been mapped by restriction endonuclease cleavage is too small to allow any conclusions to be drawn about the

Table 30.3. The distribution of 4 independent biological properties characteristic of Asian variola major virus according to the geographical origin of the strains tested<sup>a</sup>

Source of variola virus strains	Number of biological properties <sup>b</sup>				
	0	1	2	3	4
Indian subcontinent	0	0	0	5	13
Western Africa	4	2	1	0	0

<sup>c</sup> Chimp 9 and MK-7-73 (see Table 30.2).

relationship of these "whitepox" isolates to other strains of variola virus from western or central Africa. However, comparison of 4 biological characteristics of 32 variola virus strains originating from the Indian subcontinent, western Africa or Zaire with those of the "whitepox" strains Chimp 9 and MK-7-73 (purportedly recovered from primates captured in Zaire) showed that these "whitepox" isolates had the same group of biological characteristics as the great majority of strains of Asian variola major and were quite unlike 12 strains of variola virus derived from western Africa or Zaire (Table 30.3). Dumbell & Huq (1986) concluded that these two "whitepox" viruses (Chimp 9 and MK-7-73) "did not enter into the chains of transmission which maintained human variola in West Africa".

In summary, and in view of the results set out in the next section, it seems likely that the "whitepox" virus isolates made in Moscow were due to laboratory contamination with Asian strains of variola virus.

#### "White clones" ("variants") of monkeypox virus

Seeking an explanation for the recovery of whitepox virus strains from the tissues of several species of wild animals from Zaire, Dr Marennikova postulated that they may have arisen as "white clones" of monkeypox virus, which was known to infect non-human primates in that country (see Chapter 29). Several investigators (Bedson, 1964; Gispén & Brand-Saathof, 1972) had previously isolated white pock mutants of monkeypox virus, but

found them to resemble the parental virus rather than variola virus in properties such as species-specific antigenicity (Gispén & Brand-Saathof, 1974) and the pattern of their intracellular polypeptides (Harper et al., 1979). In this section attention will be focused on two reports of what Marennikova and her colleagues call "stable white clones" recovered from stocks of monkeypox virus that had been maintained for several years in the Moscow laboratory. All these "white clones", recovered either as pocks on the chorioallantoic membrane (Marennikova et al., 1979) or from organs of hamsters that had been inoculated some weeks earlier with the monkeypox virus material (Marennikova & Shelukhina, 1978), were identical; they were indistinguishable by biological tests from the Zaire and Bithoven "whitepox" virus isolates, which have now been shown to be variola virus.

In view of the importance of this claim as to the origin of "whitepox" viruses, from the point of view of the feasibility of smallpox eradication, the WHO Smallpox Eradication unit organized a series of studies to determine whether these results could be independently confirmed. The studies in question were conducted in the WHO collaborating centres in London and Atlanta. Dumbell & Archard (1980) reported on 17 white pock mutants recovered on the chorioallantoic membrane from their own stocks of the Copenhagen strain of monkeypox virus and compared their biological characteristics and DNA maps with those of wild-type monkeypox virus, the Harvey strain of variola virus, the 2 Netherlands "whitepox" isolates, 2 Zaire "whitepox" viruses and 2 "white clones" recovered from monkeypox virus by passage through hamsters (Marennikova & Shelukhina, 1978). All the "whitepox" viruses and the 2 "white clones" had DNAs that were virtually identical with that of variola virus (Table 30.4). The monkeypox white pock mutants differed among themselves in both genome maps and biological properties (Table 30.5). Some, which had been recovered after serial passage of the monkeypox virus stock at high concentrations, showed complex genome changes, with deletions and transpositions; some showed minor differences from wild-type monkeypox virus, others were indistinguishable from it. In all cases the DNA maps were readily distinguishable from those of variola and "whitepox" viruses (Fig. 30.2).

(1985).<sup>d</sup> Not tested.

Studies at the Centers for Disease Control (CDC), in Atlanta, confirmed the results obtained in London. Four white pock mutants—2 derived in Atlanta from CDC stocks of a monkey strain of monkeypox virus (Copenhagen) and 2 from their stocks of a human strain (Congo)—resembled monkey-

pox virus in both their DNA maps (Table 30.4) and their biological characteristics (Table 30.5). On the other hand, Esposito et al. (1985) reported that isolations of white pock mutants made by a member of the staff of the Moscow laboratory working in the CDC, but not using the glovebox facility, had

Fig. 30.2. **A:** Physical map locations of *Hind*III, *Xho*I and *Sma*I cleavage sites in DNA from variola, "whitepox" and monkeypox viruses: Harvey strain of variola major, Netherlands "whitepox" 64-7255, "whitepox" *Mastomys* (= Moscow RZ-10-74), Monkeypox Copenhagen, and 4 white pock mutants derived from Monkeypox Copenhagen (Monkeypox h2, h7, h8 and h15. (Based on Dumbell & Archard, 1980.) **B:** Dendrogram illustrating the similarities and differences between these DNAs. Presence, absence or impossibility (because DNA molecules were too small) of coincidence of the cleavage sites illustrated was determined after aligning all maps on a common *Hind*III cleavage site about 60 kilobase pairs from the left-hand end of the molecule; the results were then analysed as described by Gibbs & Fenner (1984), using the squared Euclidean metric (number of attributes = 60). The "index of dissimilarity" has no absolute value, but illustrates the close resemblances between the DNAs of variola virus and the 2 "whitepox" viruses, and between the DNAs of monkeypox virus and the 4 mutants derived from it.

biological properties and DNA maps identical with those of variola virus. On the basis of a detailed analysis of all the data, these authors concluded that "the spontaneous production of whitepox from monkeypox virus would be genetically impossible", and that "the whitepox viruses recovered from monkeypox virus stocks had originated exogenously".

This work was carried out in 1978 and 1979, and in an assessment of the situation in 1980, on the eve of the declaration of smallpox eradication by the Thirty-third World Health Assembly, Fenner et al. (SE/80.154) concluded that "the variety of mutants derivable from monkeypox in the laboratory does not present any greater threat to the success of smallpox eradication than

does the existence in nature of orthopoxvirus species other than variola".

### **Conclusion: There is No Animal Reservoir of Variola Virus**

The evidence reviewed in the foregoing pages suggests that smallpox was indeed a specifically human disease. Variola virus is a distinctive species; DNA analysis of strains of widely differing virulence for man (variola major and variola minor viruses) shows that their DNAs are very similar, but quite different from those of any other species of orthopoxvirus or from those of any viral mutants that have been recovered under conditions that precluded the possibility of laboratory contamination. Variola virus has a narrow host range; besides man the only animals in which serially transmissible infection is known to have occurred are chimpanzees, orang-utans and one species of monkey. The "whitepox" viruses isolated from a variety of animals between 1964 and 1975 are strains of variola virus. The most acceptable explanation is that all of them were laboratory contaminants.

The laboratory evidence must be seen in both epidemiological and evolutionary perspectives. Apart from known contaminants (the Bithoven viruses), the 4 "whitepox" viruses were recovered from areas of Zaire in which human monkeypox occurred and continues to occur more frequently than anywhere else in the world. The isolation rate in Moscow for the recovery of a virus from wild animals was high (4 out of 61 animals from the areas that were tested, compared with none of 930 animals from the area tested by the Centers for Disease Control, Atlanta, primarily in a search for monkeypox virus). Since human monkeypox is a zoonosis and intensive surveillance in selected areas of Zaire between January 1982 and December 1984 revealed 210 cases of human monkeypox, of which 144 were thought to have an animal source (see Chapter 29), there is clearly the kind of contact between humans and animals in these tropical rain forests that would make infection of humans with variola virus likely, if indeed it occurred in the animals there. However, all cases of "suspected smallpox" in western and central Africa since 1970 that were due to orthopoxvirus infection have been shown by epidemiological and laboratory investigation to have been caused by monkeypox virus.

### **MATERIAL STORED BY VARIOLATORS**

Variolation was a matter of concern as a source of outbreaks of smallpox during the operations of the Intensified Smallpox Eradication Programme in Afghanistan, Pakistan and Ethiopia (see Chapters 14 and 21). In addition, it was known that an outbreak in northern Yunnan Province in China in 1958 was due to variolation, 126 cases having occurred a year after the last known case in that subregion. Late in 1984 it was learned from Dr Jiang Yutu, in a personal communication, that there had been other outbreaks of smallpox in North China (Nei Monggol Autonomous Region (Inner Mongolia) and 2 nearby counties in Shanxi Province) which were ascribed to the activities of variolators and the first of which occurred some 6 years after the last reported cases of smallpox in these regions (see Chapter 8, Table 8.13; and Chapter 27). The explanation for these outbreaks (Jiang Yutu, 1985; and personal communications, 1984, 1987) appears to be that variolators in Shanxi and adjacent parts of Inner Mongolia continued to keep variolation material, stored with honey in sealed jars, and maintained its potency by annual passage in susceptible family members and by the addition of fresh material to the jars. The 1962-1964 and 1965 outbreaks were initiated by such variolated persons but the chains of transmission have not been elucidated. The occurrence of these outbreaks long after smallpox had been eradicated from China led to measures that eliminated this source of the disease and no case of smallpox has been recorded in the country since 1965.

Apart from these episodes in China, which did not come to the attention of WHO until 1984, major concern with the danger of variolators' material causing outbreaks of smallpox after the interruption of transmission centred on Afghanistan. Tests for viable virus in material collected from variolators there gave positive results in one sample 9 months after the material had been collected from a patient; all the others were negative long before this (see Chapter 14, Table 14.15). All the variolators who were questioned about their mode of operation said that, if it was available, they preferred to use fresh material (from a recent case), and as smallpox became less common they usually added fresh

scabs or pustule fluid to their stored material whenever possible. One sample tested contained herpesvirus particles, doubtless derived from a misguided attempt to keep viable stocks for variolation.

Within scabs, out of sunlight and in cool surroundings, viable variola virus can survive for several years. However, variolators' material was never held under such "ideal" conditions, and tests showed that it rarely contained viable virus for as long as one year. The major factor that now further reduces the risk presented by variolation material as a source for the recurrence of smallpox is the passage of time. The last cases of smallpox in countries in which variolation was widely practised during the 20th century occurred in 1965 (China), 1973 (Afghanistan), 1974 (Pakistan) and 1976 (Ethiopia). In Ethiopia, in which smallpox was the most recently endemic, variolation was usually carried out with fresh pustular material when an epidemic threatened, and material was rarely stored (see Chapter 21). The lapse of 10–20 years since the last cases of smallpox in the other countries has reduced the incentive to practice variolation, and even under the best storage conditions (short of refrigeration) the viability of variola virus gradually falls off. The absence of any recurrence of smallpox due to variolation for 10 years or more gives reason to believe that this practice will never again initiate an outbreak of smallpox.

### LABORATORY STOCKS OF VARIOLA VIRUS

While the existence of an animal reservoir was without doubt the most serious risk to the achievement of the permanent eradication of smallpox, the existence of stocks of variola virus in laboratories constituted and, while such stocks of variola virus are retained, will continue to constitute a real though remote risk that further cases of human smallpox could occur.

### Changes in Attitude towards Work with Variola Virus

The handling of variola virus has been subject to progressively stricter control over the years. In Jenner's day variolation was extensively practised, with no control or supervision of the way in which the virus was

handled or administered and usually little or no check on the movements of the inoculated subject. Jenner, and vaccinators after him, did not hesitate to test the efficacy of vaccination by challenge inoculation with variola virus. Variolation, which involved the uncontrolled distribution of variola virus, was not made illegal until 1840 in Great Britain and 1870 in British India, and, as has been noted above, it was widely practised in Afghanistan up to the early 1970s and in Ethiopia until as late as 1976.

Pathologists who were interested in smallpox and vaccinia experimented with variola virus as a matter of course and with few precautions, secure in the protection afforded by a previous attack of smallpox or by repeated vaccination. The attitude of virologists towards handling the virus in the 1950s is revealed in the report on experiments on viability by Wolff & Croon (1968), who stored scabs from a patient in an envelope in a cupboard in their laboratory in 1954, and tested one scab annually for the presence of variola virus. At that time reliance was placed on vaccination and revaccination of all laboratory workers, good laboratory technique, and careful disposal and sterilization of infected material and glassware. Biohazard hoods had not then been invented and work with variola virus was carried out on open benches, although special cubicles were sometimes used when the virus was handled on a large scale. In countries in which smallpox was still endemic—for example, in India, Africa and South America—material for smallpox diagnosis was regarded, with reason, as being less hazardous to handle in the laboratory than, for example, material containing the tubercle bacillus.

### Safety Regulations in Laboratories Holding and Handling Variola Virus

#### *Recommendations made in 1969 and 1974*

The first comment by WHO on precautions to be taken when handling variola virus in the laboratory appeared in the publication *Guide to the Laboratory Diagnosis of Smallpox for Smallpox Eradication Programmes* (World Health Organization, 1969a), which was prepared by 2 virologists with extensive experience in handling variola virus (Dr A. W. Downie and Dr J. Noble) and 2 epidemiologists (Dr I. Arita and Dr A. S. Benenson). The guide suggested that methods

that ensured high standards of microbiological safety should be employed and that everyone who might have occasion to enter the laboratories should be vaccinated annually. However, recommendations on physical containment were relatively simple (Fig. 30.3A)—a separate room entered via a vestibule, but no provision for sterilization of the ambient air, for biosafety hoods or for 2-way autoclaves.

Following the accidental infection of a laboratory worker in London in 1973 (see Chapter 23), virologists in the United Kingdom interested in smallpox drew up a code of safety practice (Cox, 1974). This code formalized arrangements for vaccination and revaccination and for the first time suggested the use of safety cabinets and emphasized the risk of aerosol production during laboratory manipulations. It recommended that animal inoculation should be performed only in "institutes with specially designed facilities".

During the middle and late 1970s laboratory safety in general became a much more prominent issue. There were several reasons for this, including deaths from Lassa and Marburg fevers contracted in the laboratory, the invention and development of sophisticated methods for the physical containment of infectious agents, and the widespread concern for laboratory safety engendered by the introduction of recombinant DNA technology.

#### *Safety measures recommended by WHO in 1977*

Because of this change in attitude towards laboratory safety, and the imminent achievement of the global eradication of smallpox, the WHO Smallpox Eradication unit in August 1977 organized a meeting of experts to discuss safety measures in laboratories retaining variola virus. The expert group included senior staff from the WHO collaborating centres for smallpox research in London, Tokyo, Moscow and Atlanta, and Dr J. H. Richardson of the Office of Biosafety at the Centers for Disease Control, Atlanta. Recommendations for physical containment and the packaging and shipping of specimens were drawn up (SME/77.2). Although smallpox laboratories in the WHO collaborating centres had to a greater or lesser degree already installed the physical facilities outlined in this report, it was the first official statement by WHO prescribing the kinds of physical containment necessary for holding

and handling dangerous pathogens, with strict control of entry, facilities for air and biowaste sterilization, gloveboxes (see Plate 30.3), 2-way autoclaves and biological safety cabinets (see Fig. 30.3 B), as well as the usual stipulations about vaccination and regular revaccination.

The laboratory-associated outbreak in Birmingham, England, in August-September 1978 (see Chapter 23) caused serious concern among the general public and the health authorities of many countries. Reacting to this concern, the WHO Smallpox Eradication unit arranged a meeting in Geneva in April 1979 to study the safety measures adopted in laboratories then retaining stocks of variola virus and to discuss the destruction or transfer of the virus if the laboratory concerned was not using it for research. Government officials from the 7 countries and scientists from the 8 laboratories that then retained variola virus attended the meeting and reviewed the situation (WHO/SE/79.137), with special reference to the role of national authorities in maintaining safety standards. They agreed on modifications to the WHO recommendations for physical containment in accordance with further experience with such facilities; these were issued as WHO document SME/77.2 Rev. 1 and later reproduced in Annex 9 to the final report of the Global Commission (World Health Organization, 1980). Eventually, in March 1983, the WHO Committee on Orthopoxvirus Infections, noting that the Organization, through its Special Programme on Safety Measures in Microbiology, had published a book entitled *Laboratory Biosafety Manual* (World Health Organization, 1983) which provided a standard reference for a maximum containment laboratory, recommended that WHO document SME/77.2 Rev. 1 should be withdrawn.

Over the several years after the 1977 meeting steps were taken to ensure that the facilities in the WHO collaborating centres in Atlanta and Moscow were upgraded, and new laboratories were built in each centre. It is not widely appreciated how difficult it is to build a highly secure biocontainment laboratory and maintain it properly, particularly in relation to airflow. For various reasons it took more than 3 years to construct and test the new facilities in both centres, and all research work with variola virus ceased during this period, although studies with variola virus DNA, which is not infectious, continued in

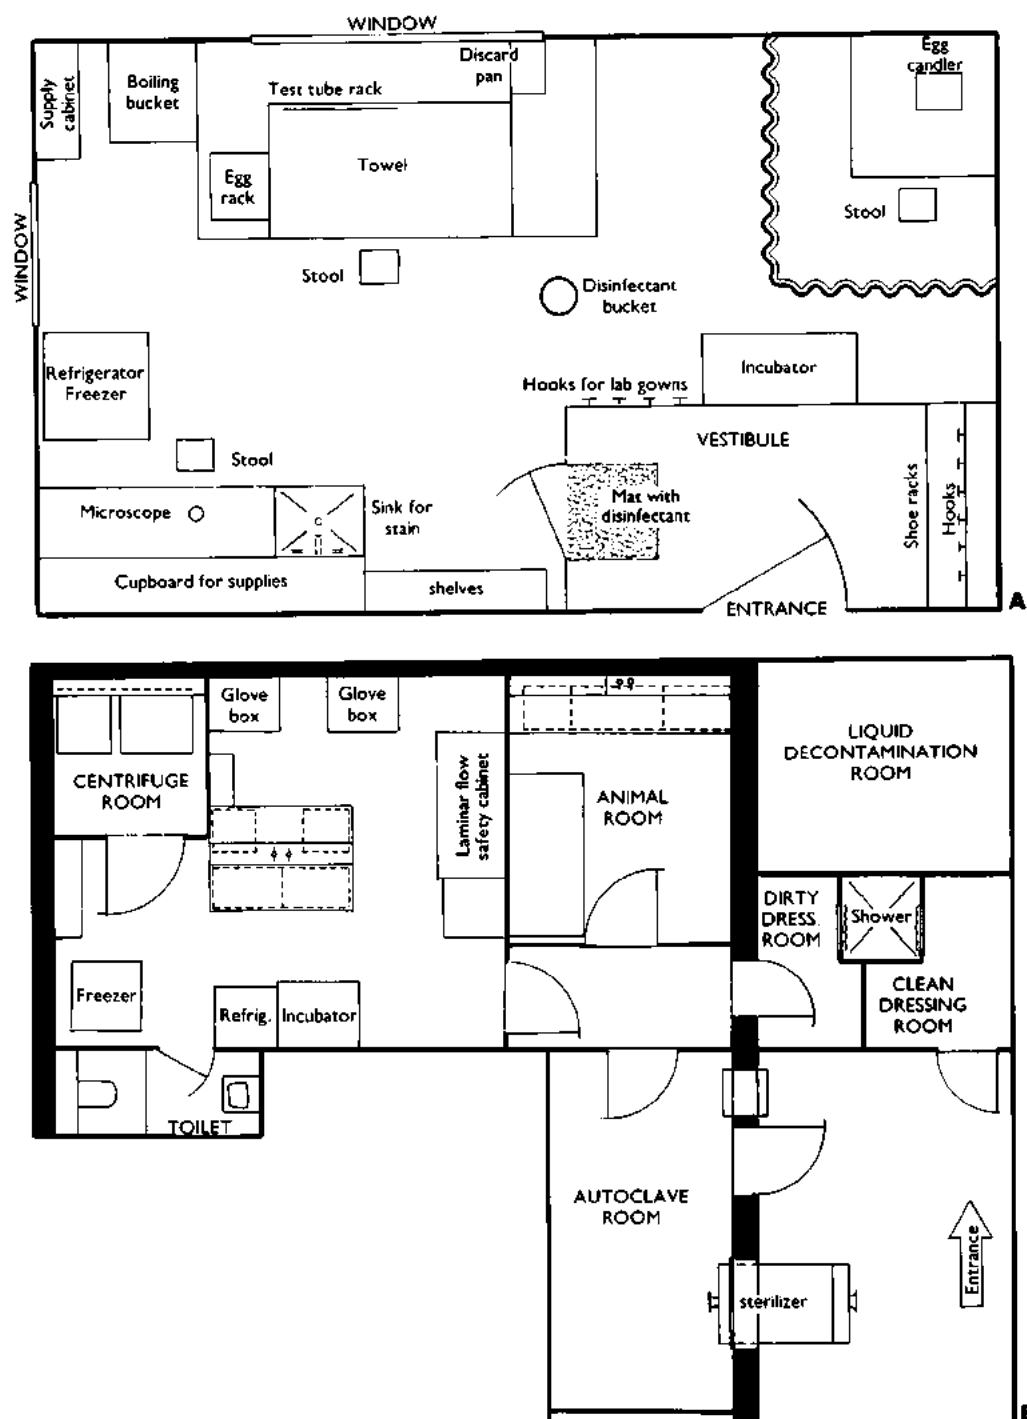

Fig. 30.3. **A:** Suggested layout for a smallpox diagnostic laboratory as conceived in 1969. (From World Health Organization, 1969a.) **B:** Plans of part of the smallpox laboratory at the Centers for Disease Control, Atlanta, GA, USA, drawn in 1979. Note the much more stringent physical containment, with access and exit of personnel through a shower and access of materials through a decontamination box and exit via a two-way autoclave. Effluent air is passed through a HEPA (high-efficiency particulate air) filter and liquid and solid wastes are sterilized by heat treatment. Within the laboratory, virus is handled within a glovebox or under a laminar flow hood and special precautions are taken with centrifugation and other laboratory manipulations.

**Plate 30.3.** Glovebox facility (Class III biological safety cabinet) in use at the WHO collaborating centre in the Centers for Disease Control, Atlanta, GA, USA. To eliminate the risk of laboratory contamination, only a single specimen was handled at a time and the cabinet was sterilized with peracetic acid before another specimen was introduced.

Atlanta. Between August 1981 and March 1983 urgent diagnostic work on specimens from cases of suspected smallpox or monkeypox was carried out in the Special Viral Pathogens Laboratory at the Centers for Disease Control in Atlanta. Work with variola virus in other laboratories that held the virus in 1979 (see Table 30.6) ceased at various times between 1979 and 1982, when their stocks were transferred to a variola virus storage facility in the Centers for Disease Control.

Two of the 19 recommendations of the Global Commission (World Health Organization, 1980), all of which were accepted by the Thirty-third World Health Assembly in May 1980, dealt with the inspection of WHO collaborating centres approved to hold and handle variola virus. It was recommended that each laboratory that still held variola virus (whether or not a WHO collaborating centre) should report annually to WHO on its safety measures and should be inspected periodically by WHO. The implementation of these recommendations has been described in Chapter 28.

### Justification for the Retention and Use of Variola Virus

The potential danger of experimentation with variola virus in a laboratory not equipped with full microbiological security facilities was dramatically demonstrated by the Birmingham outbreak, discussed in Chapter 23, some 10 months after the last known case of naturally transmitted smallpox had been reported in Somalia. In response to the concern expressed by many WHO Member States, a consultation of public health and virological experts who were not themselves involved in laboratory work with variola virus was convened in Geneva in February 1979. Its report (WHO/SE/79.135) was subsequently used by the Global Commission for the Certification of Smallpox Eradication in formulating its final report (World Health Organization, 1980). In essence, the consultation recommended that research with variola virus was justified, at least for the next 3 years, because of the problem then posed by reports of the isolation of "whitepox" viruses and the work on DNA mapping that provided a

### The Maximum Containment Laboratory

The 1977 report and the *Laboratory Biosafety Manual* recommended the use of a maximum containment laboratory for the handling of dangerous pathogens. In essence, this is a room or a few rooms (or, for veterinary laboratories handling exotic viruses, a complete laboratory building) in which special measures are taken for the physical containment of dangerous pathogens, to minimize the risk of their escape outside the laboratory. The principal features of a maximum containment laboratory are:

(1) *Controlled access.* The entry and exit of personnel and supplies are through airlock systems. On entering, personnel put on a complete change of clothing, and they shower on exit before changing back into their street clothes.

(2) *Controlled air system.* Negative pressure is maintained by an individual supply and exhaust air mechanical ventilation system with HEPA (high-efficiency particulate air) filters in the exhaust (and in the intake when necessary).

(3) *Decontamination of effluents.* All effluents from the maximum containment laboratory are rendered safe, including the shower water.

(4) *Sterilization of waste and materials.* A double-door pass-through autoclave is provided.

Properly installed, operated and maintained, these arrangements should prevent the escape of dangerous pathogens from such a laboratory. To protect personnel from infection and to minimize the risk of contamination of apparatus and cultures, an additional facility can be operated within the maximum containment laboratory. This is called the *primary containment facility*, of which there are 3 forms:

(1) a fixed "Class III" biosafety cabinet (Plate 30.3), in which material is handled via glove ports and all effluent air is passed through a HEPA filter,

(2) a flexible-film plastic equivalent of a Class III biosafety cabinet, or

(3) a positive-pressure ventilated suit, operated only in a special laboratory which provides a decontamination shower for personnel leaving the risk area.

The WHO collaborating centre in Atlanta handled all specimens of known or suspected variola virus within a Class III biosafety cabinet. One specimen was handled at a time and the cabinet sterilized with peracetic acid before another specimen was introduced. This practice enabled that laboratory to avoid completely any cases of laboratory contamination of cultures by its personnel, throughout its operations in smallpox diagnosis and research.

method of at least partially solving this problem. In January 1979, the WHO Executive Board had asked the Secretariat to recount what measures were being taken in response to the Birmingham outbreak. The Smallpox Eradication unit was able to inform the Board of the proposed consultation and the anticipated meeting on laboratory safety measures, mentioned in the previous section, which were designed to deal with the essence of the problem—namely, whether further research with variola virus was necessary and, if so, whether the laboratories in which such work was undertaken were microbiologically secure.

### Reduction in the Number of Laboratories Retaining Variola Virus

The possibility of escape of variola virus from either of the two high-security laboratories that now retain it is extremely remote. But in 1976, as global smallpox eradication appeared imminent, stocks of the virus were held by many more than these two laboratories; in fact, no one knew how many more. It was reasonable to argue that the smaller the number of laboratories holding variola virus, the lower would be the risk of the virus escaping. The Twenty-ninth World Health Assembly, in May 1976, requested "all

### Philosophical Considerations regarding the Destruction of Variola Virus

From time to time commentators in scientific journals have questioned the moral rectitude of destroying all known stocks of variola virus, on the grounds that man should not knowingly cause the extinction of any living thing. With the cloning of variola virus DNA this raises some interesting philosophical problems. Are variola virions, in an ampoule, "living things"? In fact they are inert until their genetic potential can be expressed, and the only "natural" form of living variola virus would be that found in a human being, since man was the only known host of the virus. Presumably, the periodic occurrence of cases of smallpox is not what conservationists have in mind when they argue that variola virus stocks should never be totally destroyed.

The other problem is whether the cloned fragments of variola virus can be regarded philosophically as still constituting the essence of life of that virus. Certainly, molecular biologists are, or soon will be, able to produce all the known viral products from such cloned fragments. They could even, with considerable (albeit misguided) effort, reconstitute the intact variola virus DNA molecule and thus by laboratory manipulations, the virus itself.

When viewed against the regrettable but wholesale extinction of species that results from human interventions in natural ecosystems, concern about the preservation of variola virus seems to us to be misplaced. The only criterion by which to judge the necessity for the preservation of the virus, we believe, is whether it is necessary for scientific work.

governments and laboratories to cooperate fully in preparing an international registry of laboratories retaining stocks of variola virus" but, at the same time, urged all laboratories which did not require such stocks of variola virus to destroy them (resolution WHA29.54). This resolution followed inquiries that the WHO Smallpox Eradication unit had addressed in 1975 both to governmental authorities and to the directors of 823 laboratories included in the WHO World List of Virus Laboratories. The unit had also scanned the *Index medicus* in search of references to papers on variola virus published from laboratories during the previous few decades and had written to the directors of these laboratories to find out whether they held stocks of the virus. This information having been obtained, laboratories other than the WHO collaborating centres in Atlanta and Moscow and the WHO laboratories for poxvirus research were asked to destroy their stocks or transfer them to one of the two WHO collaborating centres. Governments were asked to inform WHO of the response to this request. Prior to this, the Director of the National Smallpox Eradication Programme in India had carried out a similar survey in

that country and reported that by the end of 1976 all stocks of variola virus in laboratories in India had been destroyed (Basu et al., 1979). The situation in the 6 WHO regions in 1975 and in July 1977 is shown in Table 30.6.

Some noteworthy inferences can be drawn from this table. First, the response from both national authorities and laboratory directors was remarkably comprehensive. Apart from China, the countries that failed to respond were small in size and population and were known not to have a laboratory that had ever handled variola virus. Secondly, there were no fewer than 75 laboratories, several in each WHO region, that were then holding variola virus. Indeed, the real figure was somewhat higher, for it is known that virologists in several laboratories discovered that they did still possess variola virus, after having, in good faith, declared to the contrary; in such instances, the stocks were privately destroyed or taken to the nearest WHO collaborating centre for destruction. This widespread possession of stocks of variola virus is not surprising. Smallpox was endemic in several populous countries and importations into Europe, especially, had occurred in the recent past. In order to have "controls" for the

<sup>a</sup> Although China did not respond to the WHO letter of request, stocks of variola virus were then held at the Institute for the Control of Drugs and Biological Products, Beijing.

laboratory diagnosis of agents that they rarely handle, such as variola virus, virologists usually keep strains of these agents in their deep-freeze cabinets, for comparison with a suspicious isolate. Provided that their staff were regularly vaccinated and used good microbiological techniques, laboratory directors rightly regarded variola virus as less dangerous to handle than other agents sometimes encountered in diagnostic laboratories, such as various rickettsias. Further, even though smallpox might no longer be endemic in their country, it did not occur to them to destroy their laboratory stocks of variola virus. However, in response to the request from WHO, and bearing in mind the imminent world-wide eradication of smallpox, the directors of 57 of the 74 laboratories agreed to destroy or transfer their stocks of the virus.

*Further reduction in the number of laboratories retaining variola virus, 1977-1983*

With strong support from the Consultation on the Worldwide Certification of Smallpox Eradication, convened in Geneva in October 1977, and subsequently from the Global Commission, WHO continued to exert pressure to try to reduce further the number of laboratories holding variola virus stocks. In its final report in December 1979 (World Health Organization, 1980) the Global Commission recommended that: "No more than four WHO collaborating centres should be approved as suitable to hold and handle stocks of variola virus. A collaborating centre would be approved only if it had adequate containment facilities." Biocontainment standards had been laid down for

such laboratories (SME/77.2 Rev. 1) and it was stipulated that each laboratory that held variola virus (whether it was a WHO collaborating centre or not) should be periodically inspected by WHO.

The Birmingham outbreak had a dramatic effect on the attitudes of the directors of several European laboratories, because of Professor Bedson's suicide and the extensive press coverage of the event (see Chapter 23). By the end of 1979, 5 of the remaining 8 European laboratories holding variola virus had disposed of their stocks (Table 30.7). Every year, at the World Health Assembly, Member States continued to express concern about variola virus stocks in laboratories. Gradually, the remaining laboratories holding such stocks responded to the requests from WHO to destroy or transfer their holdings, since with the eradication of smallpox the rationale for retaining stocks of the virus in any laboratory except the WHO collaborating centres in Atlanta and Moscow had disappeared. Scientific developments, notably the cloning of restriction fragments representing the total genome of variola virus (see Chapter 2), removed the last objections,

voiced by the Ministry of Health of South Africa (see Chapter 28, Plate 28.4), and by the end of 1983 only 2 laboratories in the world, both with newly completed biocontainment facilities, still held stocks of variola virus: the WHO collaborating centres at the Centers for Disease Control, Atlanta, and the Moscow Research Institute for Viral Preparations. At a meeting in March 1986, the Committee on Orthopoxvirus Infections recommended that all stocks of variola virus should be destroyed in October 1987, subject to approval by an *ad hoc* committee to be convened by WHO.

There remains the possibility that ampoules containing variola virus may still be stored in deep-freeze cabinets in laboratories, unknown to anyone in the laboratory or indeed in the country concerned. In most laboratories deep-freeze cabinets are rarely thoroughly cleaned out, though sections of them may be. As staff replacements occur and smallpox recedes into the past, all memories of working with variola virus will be lost. Two such incidents have come to the notice of the WHO Smallpox Eradication unit—the discovery of variola virus stocks in a laboratory in California in 1979 (Emmons, 1979), and in a laboratory in the United Republic of Tanzania during the visit of a WHO international commission in 1979 (J. G. Breman, personal communication, 1979). Another possible but unconfirmed example was described in London in December 1985. The dangers posed by such forgotten material are very small provided the laboratory carries out the recommended safety measures—namely, the destruction by autoclaving of any unlabelled ampoules or any ampoules labelled “variola virus” or “smallpox virus”. This risk is hypothetical and in any case beyond the control of WHO or any other organization.

### DELIBERATE RELEASE

The United Nations (1970) and a WHO group of consultants (World Health Organization, 1970) both included the smallpox virus among some 20 infectious agents that could be used in biological warfare. However, it ranked low in suitability compared with several other viruses, rickettsias and bacteria. As the WHO consultants commented:

“Because of the effectiveness of the vaccine and the relative ease with which it can be produced

and administered, it is unlikely that smallpox virus would be used as an agent for a large-scale biological attack against countries systematically practising periodic vaccination.

“The variola virus, however, can easily be employed for acts of sabotage. Such acts, at selected points within a country, could have serious socio-economic effects unless efficiently dealt with by the public service.”

That was written in 1969. At present no country is “systematically practising periodic vaccination” and as time passes the immunity of those who have been vaccinated will wane and populations will become completely susceptible.

In 1972 many countries of the world signed a convention outlawing the use of biological weapons in warfare (United Nations, 1984). Unfortunately, as international conventions are subject to infringement, this does not completely exclude the possibility that variola virus might be deliberately released as a means of warfare. However, the risk of any such act leading to the re-establishment of endemic smallpox should not be exaggerated. As has already been mentioned, smallpox spread comparatively slowly, by face-to-face contact. Unless the public health services had completely broken down, the existence of reserve stocks of vaccine (see Chapter 28) and the capacity for the production of vaccine to be rapidly reactivated would ensure the containment of any outbreak that followed a deliberate release of variola virus. With the cessation of vaccination and vaccine production, it will become increasingly difficult for any person or group contemplating the release of variola virus to assure themselves and their colleagues of protection against smallpox. A country's resumption of vaccination against smallpox would now be interpreted as a sign that it might be considering the use of variola virus for aggressive purposes.

Deliberate release, or the threat of it, by an individual or a group, as an act of sabotage or terrorism, is remote because access to the virus is so restricted. A document made public in December 1984 (Young & Lenarcic, 1984) describes tests made in 1964 and 1965 with aerosols containing *Bacillus subtilis* as a marker. The aerosols were experimentally but secretly produced in a crowded airport in Washington, DC, USA, to test the possibility that variola virus might be released in this way and thus cause “inexplicable” outbreaks of smallpox a few weeks later in the diverse

The door is kept locked and the key retained by the director. **B:** Variola virus is stored in two nitrogen vapour phase freezers in a maximum containment laboratory at the Centers for Disease Control, Atlanta, GA, USA.

places to which infected passengers travelled. The existence of such a possibility emphasizes the need for "military" as well as microbiological security in laboratories holding variola virus stocks. It is melancholy but perhaps realistic to suggest that the possibilities of biological warfare or terrorism now constitute the chief reason for holding reserves of vaccine and for maintaining epidemiological and laboratory expertise for the diagnosis and control of smallpox.

### REACTIVATION AND EXCRETION OF VIRUS IN HUMANS

Viruses of many viral families persist for long periods in their hosts and viruses in some families are persistently (Arenaviridae) or intermittently (Herpesviridae) released into the environment. In addition, there is now a vast experience of the reactivation of latent herpesvirus infections (especially cytomegalovirus) in immunosuppressed persons, both those suffering from lymphoreticular diseases and those in whom chemical suppression of cell-mediated immunity is employed to prevent transplant rejection. In addition, steroid therapy has immunosuppressive effects and is associated with the reactivation of latent infections. Such therapies have now been practised for many years, in many countries, but no evidence has ever come to light of the reactivation of variola or vaccinia virus in immunosuppressed persons or those on steroid therapy. This supports the view elaborated in Chapter 3 that the poxviruses in general and variola and vaccinia viruses in particular do not produce persistent infections. This hypothetical possibility can be dismissed.

### VIRAL PERSISTENCE IN THE ENVIRONMENT

Although it does not cause persistent infection in man, variola virus in scabs is, for a virus, very resistant to inactivation, especially at moderate temperatures and out of sunlight. Clothing and bedding from smallpox cases, which were often heavily contaminated with virus from salivary excretions and skin lesions, were an occasional source of outbreaks of smallpox among laundry workers (England and Wales, Ministry of Health, 1928b), and virus on imported raw cotton was suspected (without

good reason, according to Dixon, 1962) of causing some outbreaks in England. However, the periods for which the virus survived to cause such infections were measured in days or weeks—not years.

Interrred corpses have also been suggested as a possible source of infectious virus (e.g., Razzell, 1976), but the only evidence is anecdotal and comes from situations in which the possibility of infection by direct contact with cases of smallpox could not be excluded. The chance of viable variola virus surviving in corpses or coffins for the length of time that has elapsed since there were numerous smallpox deaths in temperate climates seems to us to be extremely remote, and the topic does not lend itself to scientific investigation.

A more bizarre possibility has been raised by Ewart (1983). Noting that bacteria can be preserved in permafrost for years (Boyd & Boyd, 1964), he suggested that active variola virus might still be preserved in interrred bodies at York Factory on the shores of Hudson Bay in northern Canada. Six Indians were reported to have died of smallpox there in 1782, and it was the practice to inter the bodies of the dead in wooden coffins, which were placed in graves hacked out of the rock-hard earth of the permafrost. Most of this graveyard has now been eroded by the nearby Hayes river, but Ewart's contention is that variola virus could be preserved for long periods in some such way, somewhere in the Arctic. Whether viable variola virus could be released from a thawed corpse in such a way as to infect a susceptible person is a matter of conjecture. There is no scientific evidence on which to base a firm reply to speculations of this kind; one can merely say that the circumstances that would give rise to infection from such a source are exceedingly remote and impossible to study.

In whatever form the virus may persist in the environment, it is gradually inactivated, probably even at subzero temperatures (see Chapter 2). As the intervals since the last cases of smallpox in various parts of the world have extended from months to years and now to decades, this danger has lessened until it must now (1987) be considered to be very small indeed.

### "TRANSFORMATION" AS A SOURCE OF VARIOLA VIRUS

The term "transformation" belongs to an era predating the development of microbial

BY COURTESY OF P. HERRLICH, 1967

**Plate 30.5.** Albert Herrlich (1902–1970), a leading German virologist and public health expert who was Director of the Institute for Comparative Tropical Medicine at the University of Munich. He was principal author of major books on the poxviruses and on vaccination and carried out a definitive study which showed that variola virus could not be "transformed" into vaccinia virus by passage in laboratory animals or cattle.

genetics. It now has a specific meaning: the alteration of the genome of a bacterium or eukaryotic cell by the incorporation of DNA from another source. As it used to be applied to the orthopoxviruses, the term was most frequently used to describe what was regarded as the conversion of variola virus into vaccinia virus, usually by passage through cows. It is impossible to achieve any such change when experiments are carried out under conditions that rigidly exclude the possibility of contamination (Herrlich et al., 1963).

The "white clones" of monkeypox virus, described above, were viewed by Marennikova and her colleagues as examples of the "transformation" of monkeypox into variola virus, but the evidence presented

earlier argues strongly that these isolates arose because of the contamination of monkeypox virus stocks with variola virus. Likewise, there is no likelihood that either vaccinia or cowpox virus, of which suitable strains yield a great variety of white pock mutants, could give rise to variola virus by one or a few mutational steps. The clear-cut distinctions in the DNA maps of different species of *Orthopoxvirus* (see Chapter 2) preclude such a possibility.

## GENERAL CONCLUSIONS

At this time, 10 years after the last known case of endemic smallpox, there is only one credible source from which another case of smallpox might arise—namely, the infection of a susceptible person with variola virus held in storage, either in a known location (stocks held in the WHO collaborating centres in Atlanta or Moscow) or in an unknown place. The latter could be either a stock maintained for possible use in microbiological warfare or a forgotten and possibly unlabelled specimen lying in a deep-freeze cabinet in a laboratory in which smallpox diagnosis or research was once performed. The likelihood of variola virus still surviving on scabs or associated with corpses or coffins in a form that might give rise to new cases of smallpox is now extremely remote.

Unless there were a complete breakdown of health services, so that countermeasures could not be mounted, the occurrence of an accidental case of smallpox could be readily contained, as was apparent in the Birmingham outbreak. Even microbiological warfare with variola virus should not present a significant hazard, in terms of the re-establishment of smallpox as an endemic disease. Its nature would be quickly recognized and countermeasures could be taken, calling if necessary on the personnel and materials provided by WHO as part of the "insurance policy" (see Chapter 28).

### INTRODUCTION

Smallpox is the first disease to have been eradicated by concerted and determined action on a global scale. This was not achieved, however, until more than 175 years after Edward Jenner's demonstration of the use of cowpox as a vaccine and his assertion that it was capable of eliminating smallpox from the earth. The vaccine virus had been promptly and widely distributed in the world, and vaccination was eagerly taken up as a protection against a universally feared disease. However, smallpox continued to spread as sustained control efforts were beyond the capacity of many government and health structures and vaccinations were frequently unsuccessful, especially in warm climates. Through the nineteenth century and the early part of the twentieth, tens of millions of persons were affected, of whom one-fifth or more died; no country was entirely spared. A heat-stable vaccine perfected in the 1920s helped to increase the efficacy of vaccination

in the tropics, but it was difficult to produce and was not widely used.

As health systems improved and more extensive vaccination could be undertaken, the industrialized countries became free of endemic smallpox by the 1950s but frequent introductions of the disease from less fortunate countries obliged them to maintain costly national vaccination programmes and to endeavour, not wholly successfully, to protect themselves by compelling all travellers to be vaccinated. In most developing countries, few people were successfully vaccinated and smallpox was essentially uncontrolled.

A change in the approach to smallpox control was proposed in 1958 at the Eleventh World Health Assembly by a delegate of the USSR, who advocated that all countries should collaborate in a global eradication programme. This was unanimously approved by the Health Assembly the following year. At the time, 60% of the world's population lived in areas in which smallpox was endemic.

The next 7 years saw some improvement in the quality of vaccine and some countries did become free of smallpox, but the disease continued to be widely prevalent and epidemics were frequent.

In 1966, the government delegates to the Nineteenth World Health Assembly decided that increased resources were required and allocated special funds for the Intensified Smallpox Eradication Programme that was to begin on 1 January 1967. They proposed a goal of 10 years for the achievement of eradication. This was an optimistic goal, given that some 10-15 million cases were then occurring annually in 31 endemic countries or territories with a total population of more than 1000 million; that a century and a half of vaccination had yielded only modest results; that programmes would have to be conducted in most of the world's least developed countries; and that civil strife, famine and floods could be expected as recurring problems. Nevertheless, the last endemic case of smallpox occurred just 10 years, 9 months and 26 days after this programme began.

The rapidity with which smallpox was finally eradicated after so long a history of persistent transmission suggests that lessons may be derived from the experience of the Intensified Programme to benefit other initiatives in health and development. Most significant is the extraordinary achievement which was possible when countries throughout the world collaborated in the pursuit of a common aim, making use of the structures of an international organization and acting under its auspices. This made it possible for the necessary resources to be mobilized and applied to better effect, for improved methods of management and epidemiology to be introduced and widely applied, for vital modifications in strategy to be communicated quickly, and for new and often very simple techniques suited to a country's capacities and characteristics to be introduced promptly. In consequence, international confidence and accord were strengthened and a foundation was laid for other community-wide health programmes.

The smallpox eradication programme, however, cannot serve as a template for other disease control or eradication campaigns. Every disease has its own epidemiological characteristics and methods for its control which require strategies and tactics specific to it. Also, the approach taken to the eradication of smallpox differed considerably from

country to country and was continually modified to capitalize on an evolving understanding of smallpox epidemiology and to deal with different local conditions. It is important also to note that smallpox had a number of features which greatly facilitated eradication. Most important is the fact that its severity and ability to spread in any part of the world commanded both the attention and the concern of health authorities everywhere. It had no known animal reservoir; there were no long-term carriers of the virus; and a single attack of the disease conferred essentially life-long immunity. The detection of cases was comparatively simple because the rash was so characteristic and persons with subclinical infections did not transmit the disease. Finally, a highly effective, easily administered and surprisingly heat-stable vaccine, conferring long-term protection, was available by the time the Intensified Programme started. Taken together, these characteristics are unique in relation to human infections. Indeed, when the goal of eradication from all countries of the world was decided upon, its feasibility in most of the industrialized countries and some of the developing ones had already been demonstrated.

The earliest successes of the Intensified Programme were recorded in western and central Africa, where it was quickly shown that smallpox spread less rapidly and less easily than most people had thought and that the prompt detection and immediate containment of outbreaks were vitally important—facts that were to have a profound influence elsewhere. Although the 21 countries concerned included some of the world's poorest and most heavily infected, 17 of them became free of smallpox within 2 years of the start of the programme in January 1967 and the last cases were discovered in June 1970. In Brazil, too, surprisingly rapid progress was made and endemic smallpox was eradicated from the Western Hemisphere in April 1971.

The provision of adequate supplies of potent freeze-dried vaccine and the introduction of the simple bifurcated needle had a remarkable impact on the incidence of smallpox in most countries, even those in which it was not possible to mount fully satisfactory programmes. This was especially notable in eastern and southern Africa where, by the end of 1971, smallpox had been eliminated from all but 3 countries. Meanwhile, well-executed programmes, in which the detection and

**Plate 31.3.** Dr Karan Singh, the Indian Minister of Health and Family Planning, presented the World Health Organization with this bronze statue of Nataraj on 15 August 1975, celebrating at once India's Independence Day and her freedom from smallpox. The statue is now in the Executive Board lounge at WHO Headquarters.

containment of outbreaks were an important feature, stopped transmission in East Pakistan (now Bangladesh) in 1970 and in Indonesia and Afghanistan in 1972.

Serious setbacks to the global programme occurred or were first confirmed in 1972. That year Bangladesh became reinfected with the return of vast numbers of refugees immediately after the civil war that had led to its independence; Botswana was swept by an epidemic as a result of introductions of the disease from South Africa; and it became known with certainty that Iran had become endemic in 1970 and Iraq in 1971. By late 1973, however, special campaigns had succeeded in eliminating smallpox from all the reinfected countries except Bangladesh.

In September 1973, greatly intensified campaigns began in the 5 remaining endemic countries: 4 in Asia (Bangladesh, India, Nepal and Pakistan) and 1 in Africa (Ethiopia). In the densely populated areas of Asia, new methods and extra resources were required to cope with smallpox among people who moved much about their country and among the large groups of persons displaced by natural disasters or civil strife. The employment of tens of thousands of health staff in ingeniously devised, well-supervised search and containment programmes made it possible to stop transmission in Pakistan in 1974 and in the other 3 countries in 1975.

Late in 1975, personnel and additional resources were shifted to Ethiopia, then the only country in which smallpox remained endemic. There, the milder form, variola minor, spread tenaciously across a vast and sparsely settled area in which civil strife was widespread and there were few roads or health services. Using many local volunteers and helicopters in yet another type of campaign, the smallpox eradication staff contained the last outbreak, in the Ogaden desert, in August 1976. However, civil war and the exodus of many refugees brought about a reintroduction of the disease into Somalia. Experienced staff and resources from many countries were mobilized to deal with this emergency, and the world's last naturally occurring outbreak took place on 26 October 1977.

Endemic smallpox had been eradicated but the health authorities of the world had to be completely confident of this fact if they were to forego the security—and the expense—of vaccination. Close surveillance and special searches had therefore to be conducted in many countries for at least 2 years after the

last known case had occurred before international commissions appointed by WHO could be asked independently to verify the absence of smallpox. Finally, a WHO Global Commission undertook a variety of studies to satisfy itself that eradication had been achieved throughout the world, its conclusions being endorsed by the Thirty-third World Health Assembly in May 1980.

No two national eradication programmes were exactly alike, and all changed as they evolved, different elements and approaches contributing to the ultimate success. In this chapter, we try to identify the most important principles and lessons which appear to have a bearing on other community-wide health activities. Many of the conclusions are shared by other authors (Dutta et al., 1975; Foster, 1977; Sharma, 1980; Yekutieli, 1981; Hopkins, 1985; Jarrett, 1985), but differences are also apparent as each author has approached the question with a different experience and from a different point of view. Finally, we attempt the difficult task of assessing the costs and the benefits of the eradication of smallpox.

## PRINCIPLES AND LESSONS

### Political Commitment, Coordination and Implementation

For a world-wide programme against a disease to be successfully undertaken, all countries must agree to it and there must be a mechanism for coordinating and monitoring the work. The World Health Assembly provides the necessary and, indeed, the only forum in which global health policies can be agreed upon; and the World Health Organization alone has the requisite channels of communication with the national authorities through which their several programmes can be coordinated, with the support of the international scientific expertise upon which the Organization can draw. Both the Health Assembly and the World Health Organization were essential to the success of smallpox eradication.

The policy decision by the Twelfth World Health Assembly (1959) to undertake the global eradication of smallpox represented an important first step. Through the 1950s, most national governments and colonial adminis-

trations had conducted smallpox control programmes, some of which were very effective. If any disease were to be eradicated by such a widespread although uncoordinated effort, smallpox was the most likely one, given the threat it posed to all countries and the availability of an effective vaccine. However, the interest of national authorities in smallpox control waxed and waned with the varying incidence of the disease and as they became temporarily free of it or, on the contrary, were reinfected from abroad. A concerted and sustained initiative, supported by one or more bilateral assistance agencies, might have succeeded in eliminating smallpox from many countries but it is unlikely that it could have achieved world-wide eradication. Moreover, a scheme to certify that eradication had been accomplished would have carried little conviction without the credit and authority of an international agency which could mobilize respected scientists from throughout the world.

Some countries were encouraged by the decision in 1959 to begin or to intensify their own special programmes and some bilateral support was found, but 3 factors compromised the effort. The first was that the World Health Assembly did not back up its decision by the allocation of special funds, and WHO provided very few staff to coordinate or assist the national efforts and very few funds to help their work. In the majority of countries little action was taken and eradication was assigned a low degree of priority. Second was the fact that in Brazil, South Africa and some countries of eastern Africa, the prevalent form of smallpox was variola minor, which caused only mild illness and few deaths and therefore ranked low among the many other health problems. The third factor was that several large countries were not then Members of WHO. For them, the resolution of the Health Assembly had no direct bearing on their national policies and few of them provided information about the incidence of smallpox or the nature of their activities to control it.

The allocation by the Nineteenth World Health Assembly (1966) of special funds for smallpox eradication signalled a change in priorities. It served to stimulate national commitment to the idea of eradication and encouraged the backing of bilateral assistance agencies; it permitted the recruitment of additional WHO staff; and it provided additional resources for national programmes. The annual allocation of US\$2.4 million was

not large when compared to the overall need, and minuscule compared to the amounts being expended for the prevention of smallpox in the industrialized countries, but it was an important stimulus without which eradication could not have been achieved.

National support for global smallpox eradication, expressed as unanimous approval of the programme in the World Health Assembly, did not quickly take the form of effective national action, often owing to inertia though sometimes for lack of resources. WHO could not compel a Member State to meet the responsibilities to which it had pledged itself, but by the exercise of moral suasion it was eventually able to overcome reluctance on the part of national authorities. This required WHO staff to play an active role in advocating that eradication programmes should be started and sometimes meant a direct approach to heads of state or other senior national figures when officials at lower levels failed to respond. This encouragement of national programmes and the subsequent support of their work would not have been possible without a technical staff in WHO of sufficient size. From 1959 through 1966, there were at most 1 WHO medical officer in WHO Headquarters and 4 or 5 with field projects who were engaged specifically in smallpox eradication—too few, and with insufficient funds at their disposal, to have any significant impact. In theory, the WHO representatives who were resident in most countries in which smallpox was endemic might have stimulated the development of eradication programmes, but each was responsible for coordinating all the WHO-supported activities in a country and served as a technical resource for other health projects. Few had any particular experience of smallpox eradication or the time to devote to it. As additional funds became available, the number of WHO smallpox eradication programme staff the world over increased to 50 in 1967 and eventually to more than 100. Their professional expertise was to prove essential.

At first, many senior WHO and national staff had believed that management skills only were required. The needs, as they perceived them, were simple and straightforward: to procure sufficient vaccine and to organize vaccination programmes. They believed that generalist managers, rather than epidemiologists or other specialists, were sufficient for this task. It was apparent from

the beginning, however, that the challenge was far greater than the straightforward application of vaccine. It was necessary to adapt vaccination programmes to different administrative, socio-cultural and geographical situations and to devise mechanisms to monitor and assess the work, in terms not only of the numbers of vaccinations performed but but also of their effect on the incidence of smallpox. A better understanding of smallpox epidemiology was required in order to refine the strategies and tactics. Better methods for vaccine production were needed, as were improved instruments for vaccination. It was also important to determine with certainty that there was no natural reservoir of smallpox and to demonstrate that the clinically similar and virologically related disease, human monkeypox, was not a serious threat to the programme. Complementing the staff of physicians was a cadre of non-medical staff, termed "operations officers", who proved to be invaluable in dealing imaginatively with the complex logistics of programme implementation. This network of professional WHO staff, although small in number compared to the tens of thousands of national staff, facilitated the rapid communication of new information throughout the world and assisted in adapting and applying it to national programmes.

In summary, the commitment of the World Health Assembly to a programme of global smallpox eradication provided encouragement to national health authorities to undertake programmes in their countries, an encouragement strengthened by the demonstration in previous years and in a number of developing countries that eradication was practically feasible. However, more was required than good intent and expectation. Meaningful levels of national and international support were essential, as well as mechanisms to harmonize the many different ideas and plans of multilateral, bilateral and national organizations.

### **The Importance of a Special Programme**

Smallpox eradication was conducted through a specifically targeted and time-limited special programme with funds allotted specially for it both in the WHO budget and in most national budgets, and with full-time technical staff assigned responsibility for its supervision. In this respect it may be

regarded as the type of categorical programme the conduct of which remains a contentious issue of health policy, especially in developing countries (Vittachi, 1985). Yet, it made important contributions to the development of health services because, far from being separately or autonomously administered, it worked with and through the existing national health service structures and had to coordinate its activities with those of other programmes. The basic health services network, for instance, constituted the foundation of the disease-reporting structure, and in all countries this had to be greatly improved by training and supervision in order to become effective and to provide quickly the accurate information on which the containment of smallpox depended. Immunization programmes were strengthened in many countries as smallpox eradication teams undertook to provide other vaccines, such as BCG, measles, yellow fever and DPT, and assisted with the transport of personnel and supplies for other programmes. Some participation of the existing health staff in vaccination and in search and containment activities was required everywhere because of the small numbers engaged full-time in smallpox eradication. In consequence, many thousands of health staff received training in the execution of vaccination programmes and in field epidemiology; in many cases the only field supervision they received was provided in the course of their smallpox eradication work. A substantial number who now occupy senior positions in national and international organizations are successfully applying methods used for smallpox eradication in programmes against other diseases. These methods include the use of surveillance systems for management and assessment, sample survey techniques to measure performance, and the use of disease-recognition cards to help in case detection.

Experience in the programme demonstrates 3 principles of importance to health policy decisions: (1) the provision of disease control services which reach all persons in the community requires strategies and systems of management for which traditional health care delivery systems are ill-equipped; (2) special programmes to deal with health problems of general concern offer the advantage of attracting both resources and community support; and (3) the significant improvement in efficiency and supervision that can often be realized in special programmes may well

offset the additional costs they sometimes entail.

#### *The delivery of community-wide services*

Health officials in most countries have recognized that traditional health care systems—comprising a network of medical practitioners, health centres, and hospitals—have been designed fundamentally to provide therapeutic services for those who seek help and are ill-equipped to deliver preventive and other services which must reach all or most persons in a community. The limitation of traditional health care systems has been that only a proportion of the population, usually the better-educated, has taken the initiative to seek its services and only some of them have benefited from what preventive services have been offered. Few in the health care system have had the training that would enable them to design or implement programmes for the delivery of services to the whole of the population. Just as, in the 1950s and 1960s, most endemic countries assigned special teams to provide smallpox vaccination, so did they have special teams and programmes to deal with tuberculosis, yaws and malaria, for vector control, for family planning and so on.

The experience in national smallpox eradication programmes confirmed that the existing health care structures were inadequate to deal with community-wide programmes of disease control. Health centres, for example, were customarily directed by physicians or others whose training and preoccupation were with curative medicine, whose management skills were limited, who rarely left the health centres and whose work was seldom supervised. Few centres gave vaccinations of any type and, when they did, often used vaccine that was not properly stored or handled. The cases of smallpox that were seen were only occasionally reported and then usually with great delay; outbreaks were rarely contained. The hospitals performed even more poorly, the inadequacy or lack of isolation procedures actually serving in many instances to augment the transmission of smallpox; even the hospital personnel themselves were often unvaccinated. Travelling teams of smallpox eradication staff endeavoured to alter practices and procedures but only when the personnel of health centres and hospitals were trained and regularly supervised by smallpox eradication programme

staff did the performance improve significantly.

It became apparent that in all countries there was a need for a specially dedicated and trained professional staff at all levels to decide and coordinate the strategy and tactics of the smallpox eradication programme and to modify these according to local needs, to develop reporting and surveillance systems, to undertake case-detection and containment measures, and to train local health staff in vaccination procedures and the proper preservation of vaccine. There was a need, too, to seek the support of village leaders and, through them, the acceptance and participation of the population. Such activities were alien to most traditional health care units.

The necessity of providing far more than curative care in order to meet the health needs of the community was recognized at the International Conference on Primary Health Care, held at Alma-Ata, USSR, in 1978. It identified primary health care as the key to this goal, being composed of a group of activities encompassing promotive, curative and rehabilitative services for all in the community.

Primary health care is often discussed as though all its activities could be pursued in a like manner, and indeed the skeletal structure of the traditional health care system can sometimes serve as the base for both preventive and curative services. As was apparent in the smallpox eradication programme, however, a different orientation and training of personnel are required for community-based programmes whose objectives are more broadly defined in terms of preventive and other disease control activities intended to reach all in the community. If directed by physicians with traditional training, the standards of the traditional service for the delivery of health care will usually be assessed by the level of training and skill of its practitioners, the quality and sophistication of its facilities and the numbers treated. In contrast, community-wide programmes—whether preventive (such as those for immunization or family planning), curative (such as those for oral rehydration or for the therapy of yaws or malaria), or a combination of the two—require that the standards of performance be assessed in terms of success in dealing with health problems in the community. Such programmes require active outreach through public education and persuasion to ensure their acceptance, the provision of services at a

site and time convenient to their clients as well as methods, such as surveillance, to measure the degree of success. Based on the experience in smallpox eradication, few traditional health care systems have been designed or their personnel equipped to handle both types of activity, and thus curative medicine has remained their dominant concern.

#### *Attraction of resources and community support*

Special-purpose programmes to achieve certain clear and specific objectives, usually within a finite period of time, have usually been better supported and financed by politicians and the public alike than have programmes, however laudable, whose health goals have been less explicitly defined. Thus, a programme to eradicate smallpox or to prevent poliomyelitis has had more appeal than one to develop the basic health services; indeed, almost without exception, public service organizations deal with particular diseases (e.g., poliomyelitis, tuberculosis or cystic fibrosis) or groups of diseases (e.g., cancer or lung diseases). Such programmes can serve broader objectives in the development of the health services, as did smallpox eradication, but support for health programmes that have lacked a categorical focus has often proved difficult to obtain.

Such special-purpose programmes are particularly important in public health because it is always more difficult to obtain a political commitment to and financial support for public health programmes than for those involving curative medical services. There are several reasons for this. First, political leaders are more readily persuaded to provide funds for curative services which, with their hospitals and health centres, are more tangible than a community-based programme. Secondly, the physicians who are most likely to be consulted regarding needs and priorities in health care are clinicians, who are more numerous and usually more influential than public health physicians; lacking a public health perspective, they tend to favour the development of clinical facilities which they will use. Thirdly, those who are the most disadvantaged and have the greatest need for community-based health services are usually the least influential politically. Thus, special-purpose public health programmes which can command attention provide an important balance to the traditional biases in allocation of health resources.

Special-purpose programmes are also associated with intensive publicity, which provides an opportunity to educate the population regarding the desirability of selected health interventions. For example, comparatively few people will voluntarily seek to be vaccinated, but more than 80% can usually be reached during the course of a well-publicized and well-executed mass campaign. As Jamison (1985) has pointed out, China's remarkable improvements in health over the past 30 years can be attributed in substantial measure to its special health campaigns, of which there have been 4 or 5 each year.

On a global scale, there is no better recent illustration of the potential for heightened support for community-based health programmes with specific objectives than WHO's Expanded Programme on Immunization, whose goal, established by the Thirtieth World Health Assembly in 1977 (resolution WHA30.53), is to provide 6 vaccine antigens to children throughout the world by 1990. This effort was augmented by UNICEF's Child Survival and Development Revolution and was subsequently endorsed in the United Nations (Mandl, 1985). International support of unprecedented magnitude was mobilized, national governments responded with special programmes and, as a result, levels of immunization coverage significantly increased in many countries.

#### *Efficiency and supervision*

Special programmes which involve the large-scale delivery of services permit economies to be realized and can facilitate better management of supplies and equipment than is possible when services are provided only in established health centres or practitioners' offices. Immunization programmes are a case in point. The cost of a dose of vaccine in multiple-dose containers is far less than that of the same dose individually packaged. To take full advantage of this, however, all or most of the contents of the larger container must be used at once, because vaccines deteriorate rapidly after the vial is opened; this is most easily accomplished in a large-scale campaign in which large numbers of people are vaccinated each day. Another but more difficult approach is to assemble large numbers of children at clinics on special vaccination days.

The efficient use of vaccine is also more readily achieved when a few vaccinators

perform many vaccinations than when many health centre staff each perform a few. Throughout the course of the smallpox eradication programme, there were recurring problems in ensuring proper vaccination technique and the proper sterilization of instruments by hospitals and health centres. Despite frequent visits by supervisory smallpox staff, many health centres in all countries regularly stored reconstituted vaccine far longer than the 1 day that was prescribed and ignored or were unable to cope with refrigeration failures. Although similar problems affected vaccination teams, it proved far easier to supervise, say, 10-25 vaccination teams than 100-250 health centres.

### Definition of Objectives and Goals

From 1967, the most important difference between the Intensified Smallpox Eradication Programme and the previous efforts was that the strategy and tactics were decided in terms of a clear ultimate objective—a nil incidence of smallpox. Although this objective is implicit in any eradication programme, progress before 1967 had been measured primarily by the numbers of vaccinations performed; the reporting of cases was considered so deficient as to be meaningless (WHO Expert Committee on Smallpox, 1964) but nothing had been done to improve its quality. Focusing on the objective of a nil incidence meant that the reporting of cases had to be improved and surveillance systems and field epidemiology developed. New methods were devised for discovering cases and containing outbreaks; resources were allocated in such a way as to provide for particularly intensive efforts where the incidence was highest, at times when transmission was most susceptible to interruption and in places where the risk of spread was greatest. In effect, this approach served to blend management with epidemiology.

Logic suggests that any disease control programme should provide continuous measurements of its impact on incidence and that these in turn should dictate changes in strategy and tactics. In fact, this is seldom the case even today. Most authorities ignore such information or dismiss efforts to obtain the data as being too difficult. Instead, progress is assessed in terms of activity, such as the numbers of vaccinations performed or of patients treated. Several countries in the early

1960s reported with satisfaction that they had vaccinated half or more of their population against smallpox each year, yet the incidence remained high owing to the use of poor vaccine and to lack of supervision. This clear indication that something was amiss with the management of the programme or the efficacy of the vaccine was ignored, however.

Although progress in the Intensified Programme was gauged primarily by the reduction of smallpox incidence, subordinate programme goals were also established in each country and area. They closely followed the principles for good management enunciated by Austin (1979), being specific, measurable, realistic and dynamic. For example, mass vaccination campaigns were expected to result in more than 80% of the population in each area having a vaccination scar. Assessment teams could easily determine the proportion of the population with a scar and, as experience showed, this goal could readily be achieved with a reasonably effective campaign. As programmes improved, this target was made more rigorous, it being required that 80% of those under 15 years old and sometimes 80% of those under 5 should have a vaccination scar. Although more difficult, these standards were not beyond attainment. For successful primary vaccination, take-rates of 95% or more were established as the standard, one which could be readily measured and was tolerant of error since rates of 99% and more were customary under optimal conditions.

From 1974, standards were also established for surveillance and containment. They established as goals that 75% of outbreaks should be discovered within 2 weeks of the onset of the first case, that containment of the outbreak should begin within 48 hours of its discovery and that no new cases should occur more than 17 days after containment had begun. As the incidence of smallpox decreased or ceased, other standards for the measurement of performance were developed which related to the population's knowledge of a reward for reporting cases and the completeness of reporting of other diseases, such as chickenpox.

The various standards were of the greatest value when the data were promptly collected, analysed and used as management guides for programme action. The knowledge by those collecting the information that their data were being promptly put to use contributed

greatly to the development of the system and to better performance. There was a limit, however, to the number of standards that could be effectively employed. This became evident during the concluding phases of global eradication as more standards were adopted and their stringency was increased: a growing volume of data accumulated, only a portion of which could be satisfactorily analysed and interpreted for use. It was apparent that a few indicators of overall performance, closely followed, were more valuable than a broad spectrum of indicators expressing the measure of many different aspects of programme execution.

### Quality Control

Methods to ensure that smallpox vaccine was potent at the time of its use, that vaccination coverage met the expected goals, and that progress was being made in diminishing smallpox incidence all represented forms of quality control. Before 1967, their application was infrequent. In both industrialized and developing countries, vaccines, even at the time of manufacture, often failed to meet the accepted international standards; few independent national testing centres monitored vaccine quality; and few health service staff examined the vaccinated after one week to determine whether their vaccinations had been successful. In many countries, large numbers of vaccinations were regularly reported but seldom was there confirmation of this by sample survey to check vaccination scars. It was known that the cases of smallpox that were reported represented only a fraction of the total but even these data were seldom reviewed to determine epidemiological trends or patterns of incidence.

The evident disinterest in quality control which characterized smallpox control programmes before 1967 is difficult to understand, but in fact it typifies large segments of current public health and medical practice. In many countries, for example, biological and pharmaceutical products are accepted and used with little assurance of their potency or purity and with little confidence that they have been properly refrigerated. Even the most elementary measurement systems, such as the enumeration of deaths by cause and the incidence of important diseases, are manifestly deficient. Where systems exist for the routine collection of information, the data,

more often than not, are consigned to statistical reports. The fact that the concept of surveillance, although simple in principle, proved so difficult to apply, reflected the lack of experience with measurement throughout the health field and, indeed, the lack of programme goals which would encourage such measurement.

### Programme Management

Multinational, cooperative health programmes are inevitably difficult to manage, given the realities of national sovereignty and the intrinsic problems of international organizations. The smallpox eradication programme could not operate as a monolithic structure, like a military command; rather, it was obliged to function in a collegial structure of many independent national programmes, each with its own administrative traditions and socio-cultural patterns, and utilizing resources from many different sources. It was a programme in which WHO, the coordinating organization, provided only a small proportion of the resources and had no authority with respect to national programmes other than that of moral suasion. Authority and responsibility within WHO itself were highly decentralized, each of its 6 regional offices enjoying a substantial degree of autonomy. With its functions and its structures at the time, the Organization was better suited to the implementation of local or regional programmes than to the execution of a world-wide programme which required international mobilization and the selective allocation and re-allocation of resources on a global basis.

Other global health programmes are confronted with similar challenges today. An effort is therefore made here to identify factors in management which contributed to the eradication of smallpox and which might facilitate more effective and better coordinated programmes of other types.

#### *The network of professional staff*

Because a hierarchical structure of international and national staff was not possible, other mechanisms had to be found to coordinate planning and to ensure continuity in the execution of the work, to control the quality of vaccines and of performance alike, and to

assess and redirect the programme as it evolved. Within WHO itself, the successful accomplishment of these tasks depended primarily on the recruitment of capable professional staff who could be given substantial latitude to make decisions, who could be assured of the funds, manpower and administrative support they needed, and who could be provided with leadership by example and exhortation rather than by directive. In the broader reaches of the programme much depended on the extent to which continuing close communication could be maintained between the national and the international staff, on their degree of mutual respect, and on the level of their common understanding of problems and needs.

A unit at WHO Headquarters with overall responsibility and accountability for all activities related to the programme proved to be essential. At first, the responsibility for a number of activities directly pertaining to smallpox eradication was scattered among a variety of units. The testing of smallpox vaccine and the development of its production were the concern of one small unit which had to deal with the entire field of biological products; notifications of smallpox cases were received by the units concerned with the application of the International Health Regulations and with the compilation of international health statistics; and yet another unit, concerned with virus diseases, dealt with smallpox research. The Smallpox Eradication unit gradually assumed the responsibility for all the activities that concerned the programme and they subsequently became more effective and more responsive to the programme's needs.

More rapid progress might have been possible if, from the beginning, there had been special staff to handle two other activities—public information and soliciting contributions from donors. There was a need to publicize widely what was being done, and where and how, in order to encourage national authorities and the participating staff and to recruit support from donors. WHO's public information office did what it could but was unable adequately to meet this need as it was small and had to serve the Organization's many other interests and programmes. Use of the *Weekly epidemiological record* to publish a full and candid account of progress and problems in the programme at intervals of 2 or 3 weeks served well to inform the public health community, but it was not especially helpful

in stimulating coverage by the mass media for the information of a broader public. A marked change occurred in 1977, when a full-time public information officer joined the smallpox eradication programme. His efforts proved vital to fostering public confidence that eradication had been achieved and that vaccination could be stopped. There were no professional staff in WHO, however, whose full-time responsibility it was to solicit voluntary contributions even though two-thirds of all international funds for the programme were expected to be provided from this source. The staff of the smallpox eradication programme undertook to raise these funds as best they could but they lacked the expertise, the necessary political contacts and the time, and their success was limited.

The Smallpox Eradication unit at WHO Headquarters provided a central point of contact for those outside the programme, whether scientists in research or vaccine production laboratories, potential donors, possible candidates for service, or the media. Because the unit needed to keep abreast of the latest developments to disseminate current technical information about the programme as widely as possible, frequent and regular communication between the scientific and public health communities and the staff of the unit was encouraged. This facilitated the rapid application in practice of new developments and benefited other operations as well.

A counterpart professional group of at least 2 or 3 persons in each of the 4 WHO regions in which smallpox was endemic would have been invaluable, particularly because of WHO's decentralized structure, but, although this was strongly encouraged, it was implemented in only 1 region. Consequently functions that might more logically have devolved upon the regional offices of WHO often had to be undertaken from Headquarters; national programmes were not always adequately supported or monitored; and the global coordination of activities was less satisfactory than it might have been.

For national programmes, an accountable and responsible professional person, preferably appointed to deal exclusively with smallpox eradication, was considered essential by WHO as a locus of contact and for the planning and implementation of the programmes. Each country was therefore requested to designate a specific person to be responsible for smallpox eradication rather than simply an office or a section of the health

ministry. This proved effective except in countries where officials were frequently transferred. However, 3 functions which were customarily the responsibility of parts of the ministry not directly concerned with disease control often presented special problems: case reporting, quality control of vaccine, and public education.

The national notification of cases was often the responsibility of a statistical unit which mechanically recorded such data as were received, showed little concern with the completeness of notifications and was not responsible for initiating action based on the reports received or compiled. Such systems seldom improved unless the smallpox eradication officer assumed the responsibility for the notifications of smallpox cases and used the data for monitoring the programme and allocating resources. This assumption of responsibility, however, often did not occur until many months or years after programmes began.

The quality control of smallpox vaccine was a problem in most countries which produced their own vaccine. Usually they had no national control laboratories and the production laboratories themselves were the ultimate arbiters of quality. Although it was WHO policy to have a WHO collaborating centre test all vaccines used in the programme, the laboratory directors often opposed this and sometimes refused to submit samples. The national smallpox eradication programme officers had no authority to enforce the policy and so it was frequently necessary for senior WHO staff to intervene with higher-level government officials. Compliance, however, was seldom easily achieved, and in a few countries substandard vaccines continued to be used even though the problem was known and recognized.

Responsibility for health education was usually assigned to a special unit in the ministry of health, but such units were seldom either adequately staffed or especially able or imaginative. Few contributed significantly to smallpox eradication campaigns, most educational efforts being mounted by regional and local smallpox programme personnel who pragmatically developed materials as required.

Overall, the basically collegial management of the programme functioned surprisingly well, its principal handicap being the lack of adequate numbers of senior staff at WHO Headquarters and in the regional offices, in

national programme offices and in states or provinces. Paradoxically, national governments were reluctant to provide one or a few additional senior supervisory staff, even when available, although they were almost always prepared to add tens, hundreds or even thousands of vaccinators. In one of the largest countries, for instance, the national programme directorate consisted until 1972 of only 1 professional person, and in one of WHO's regional offices smallpox eradication was the part-time responsibility of a medical officer who had to deal with all communicable diseases.

#### *Personnel recruitment and training*

The competence, motivation and experience of the staff ultimately govern the success of all programmes and this was unquestionably the case with smallpox eradication. Within WHO, considerable time was required to assemble the professional staff that was needed. Except for staff at Headquarters, recruitment was the *de facto* responsibility of the regional offices. Other factors of selection sometimes outweighed those of professional competence and motivation, and the smallpox eradication staff at Headquarters were, at first, seldom consulted by the regional offices about personnel decisions. Performance was not always closely monitored and contracts were sometimes renewed irrespective of performance, or personnel who proved unsatisfactory in one post might be transferred to another that could be as crucial to the programme as their previous position. However, increasing numbers of competent staff were recruited to WHO as special efforts were made by Headquarters to identify qualified candidates through personal contacts with an informal network of reputable epidemiologists, and applications were encouraged from staff who had performed well in national programmes.

The quality of national programme leadership was initially no less uneven; as the programme progressed, however, and eradication appeared more attainable, national officials increasingly assigned direction to their more able staff, many of whom had previously demonstrated their competence in field operations. Contrary to a widely held view, most countries had more than enough competent staff who could assume positions of leadership, even if many of them lacked practical experience in management because

their supervisors had been unwilling or unable to delegate authority and accountability.

A common understanding by all the senior national and international staff of the principles underlying the programme, of its essential components, and of the more important measures of progress was as crucial to success as the quality of the staff, for on it depended the ability of the programme directors to introduce effective innovations and to adapt their programmes to the prevailing circumstances. The *Handbook for Smallpox Eradication Programmes in Endemic Areas* (SE/67.5 Rev.1), surveillance reports, national and intercountry meetings, and personal visits all helped to accomplish this. The experience in the programme in western and central Africa suggests that special training programmes of perhaps 2-4 weeks' duration for all newly assigned international and senior national staff would have been equally useful elsewhere. However, a lack of appreciation by the regional offices of the need for such courses and a dearth of senior personnel to conduct them precluded their development until 1974. At that time, the intensification of the programmes in India and Bangladesh brought in sufficient additional WHO staff and consultants and specially recruited national epidemiologists to permit training programmes to be conducted in each of the remaining endemic countries.

National smallpox eradication programmes were usually staffed by persons already engaged in smallpox control and others who were reassigned from other programmes. Most countries had many more health staff than programmes with the resources to support them and their work. Given 1-2 weeks of practical field training for smallpox eradication, a steady flow of the supplies and equipment they needed and good field supervision, most performed competently and with dedication. The quality and the nature of the supervision they received were of vital importance. The best results were obtained where WHO, national, and state or provincial supervisory staff travelled frequently into the field to review activities, to resolve problems and to work with the field staff on the solution of their problems. Monthly or fortnightly meetings at which the field staff and supervisors from different areas met to discuss progress and problems and to compare results also proved valuable.

Not only was smallpox a disease with which the ordinary villager was familiar and

that he could easily recognize, though he might confuse it with chickenpox, but it also became evident early in the programme that the villagers and their leaders, if properly approached, were usually willing—indeed, eager—to cooperate in organizing vaccination programmes and in detecting cases. From 1973, when programmes in the remaining endemic countries were intensified, many of them were recruited and trained for part-time work in these activities. Their performance, as that of other field staff, was directly proportional to the clarity of the direction provided and the quality of the supervision they received.

In brief, it was clear that comparatively few, strongly motivated and knowledgeable professionals could organize and effectively mobilize large numbers of persons and that in most countries they could count on the eager support of the health staff and the general population alike. The limiting factor was the inadequate number of motivated and knowledgeable leaders, largely because too few were recruited, trained and assigned to responsible positions.

#### *Financial and other resources*

A deficiency of resources was a continual problem, which seriously jeopardized the international effort. Despite the importance of global smallpox eradication for all countries, support for the programme was barely adequate to sustain it, even during the last months before transmission was stopped. In large part, this was due to scepticism during the early years of the programme about the feasibility of eradicating a disease. Global malaria eradication had required and received substantial resources, but it was increasingly recognized to be unattainable. In consequence, disappointed bilateral donors and organizations of the United Nations system gradually withdrew support and many declined to provide more than token help for yet another eradication campaign. Such efforts as were made to inform potential donors of the progress being made in smallpox eradication and of the programme's needs proved inadequate until 1974. An intensified, well-publicized campaign had by then begun to stop transmission in the 5 remaining endemic countries as quickly as possible, before natural or man-made catastrophes could thwart the effort. When it became evident that additional resources were indispensable, special

BY COURTESY OF D. A. HENDERSON

**Plate 31.4.** Even Snoopy, the well-known cartoon character, supported smallpox eradication. He was never vaccinated, however. (Drawn by Charles Schulz, 1976.)

funds were made available by WHO and large contributions were received from Sweden and later from several other donors. These made possible the successful, large-scale programmes in Asia, but until 1976 they were insufficient to strengthen adequately the programmes in Ethiopia and Somalia. After the last case occurred in 1977, but long before the necessary work of certifying that eradication had been achieved was completed, support for the programme waned again.

Obtaining sufficient resources in the endemic countries often proved as difficult as obtaining international contributions. Although few countries had to provide significantly more money for smallpox eradication than for their previous smallpox control work, their health budgets were small and competing needs were many. To obtain adequate resources, special appeals to national leaders were frequently required. When a nil incidence was reached and the immediate threat of smallpox was removed, however, there was a strong incentive to allocate the men, money and materials to the control of other diseases; consequently, support dimin-

ished rapidly and resources to permit certification activities were seldom more than barely adequate.

Several requirements need to be borne in mind when there is a considerable dependence on voluntary donations of money or materials from different sources: (1) quality control of donated items; (2) standardization of supplies; and (3) availability of discretionary funds.

Donations in kind to the smallpox eradication programme were primarily gifts of vaccine, which was tested by WHO collaborating laboratories to be certain that it met the accepted international standards. Although it had originally been thought that vaccine from well-established laboratories in industrialized countries would not need to be tested, it was soon discovered that some of it did not meet the standards. It was found that many governments licensed producers to distribute vaccine which had been found acceptable only by tests conducted by the producer's own laboratory, and that the least competent producers were the least conscientious in vaccine testing and sometimes certified substandard batches. As a result of these findings, a number of countries were prompted to establish national vaccine control laboratories for the first time. The quality of vaccine subsequently improved significantly, but even then occasional batches of substandard vaccine were submitted for donation.

Standardization of equipment and supplies was especially important for items that required spare parts or knowledgeable mechanics for their maintenance. For vehicles and motor cycles, the most commonly provided articles, it was best to provide models already in general use in a country. The provision of unfamiliar products meant that stockpiles of spare parts had to be created and mechanics had to be specially trained. This could be done reasonably economically on the scale that obtained in the larger countries, but it gave rise to considerable problems in smaller countries. In all countries, however, the provision of only a few vehicles or motor cycles of unfamiliar manufacture usually proved to be more of a problem than a benefit. Standardization with regard to vaccine was also important. At first, vials from different manufacturers contained amounts ranging from 15 to 500 doses (0.15–5.00 ml) of vaccine, but this complicated programme planning and confused the vaccinators; efforts were therefore made to standardize all vials of vaccine so that

they contained 0.25 ml when reconstituted. Package inserts (printed forms detailing uses and contraindications) accompanying the vaccine also proved to be a problem because each country had its own policies regarding the age for and contraindications to vaccination. Eventually, however, all producers were persuaded to use a specially prepared WHO package insert which corresponded to global vaccination policies.

Finally, it is important to note that, for a programme financed principally by voluntary contributions, it was essential to have some unrestricted funds which could be used for any necessary purpose and in any country. Most donations were restricted for use in a single country or were received as contributions in kind; only a small proportion of them were received in cash and without limitations on their use. Fortunately, funds were available under the WHO regular budget to meet programme needs for which provision was not otherwise made. In western and central Africa, for example, the USA provided for all except what were known as "local costs" (costs of petrol, vehicle repair and *per diem* allowances for the teams), which its national policy prevented it from meeting; these costs were covered by WHO. There and elsewhere the sums required were small in comparison with the totals involved, but without discretionary funds most of the programmes would not have been able to operate. Likewise, although almost all the vaccine not produced locally was provided as contributions in kind, discretionary funds were needed for the purchase of vaccination instruments and for the printing of package inserts.

### Logistics

Whether a programme functioned or failed depended upon the availability of vaccines, vaccination instruments, vehicles and other supplies. Without them, programmes stopped, the momentum was lost, smallpox spread, and morale fell quickly. It was not always easy to ensure that these items were available as needed, since the demand for them fluctuated as a result of natural and man-made emergencies, unexpected epidemics and a host of other factors. The WHO smallpox eradication programme took an active part in dealing with such problems, acting in an operational capacity rather than restricting itself to the advisory technical role that was more customary in many interna-

tional programmes. This proved helpful in countless circumstances. Being in frequent contact with national and WHO programme staff, the Smallpox Eradication unit could sometimes anticipate problems and take preparatory action and was able to evaluate requests and to respond quickly. An emergency reserve of vaccine and vaccination instruments was created which permitted these to be distributed within 48 hours of a request being received; supplies and equipment could occasionally be diverted from one country to another; and special funds were sometimes provided for emergency procurement of equipment or to pay for special consultants.

The most intractable problem, and one that was never fully solved, was the supply of vehicles. Most health ministries were short of roadworthy transport and were usually unable to provide for emergency requirements. For vehicles of foreign manufacture there was usually a delay of 12-18 months between the submission of a purchase order and their delivery but it was often impossible to gauge the need for them more than 3-6 months in advance. The difficulty was resolved in some countries by purchasing locally manufactured or assembled vehicles and in others by the local purchase of already-imported vehicles, although this was usually more costly; in some instances, special workshops were established to repair and maintain the often large fleet of unroadworthy vehicles. Better results would have been obtained if it had been possible to procure a reserve fleet of new vehicles which could be dispatched quickly when needed, and if more efforts and resources had been directed to the development or improvement of national vehicle maintenance and repair facilities.

The dispensing of and accounting for funds and the uses to which they could be put were a constant, often formidable administrative problem. In many endemic countries, small *per diem* allowances and long delays in payment all but precluded travel by the national field staff; allowances for petrol often permitted only a few days of vehicle operation each month; budgets for vehicle maintenance and repair were small; and there was often no provision for the disbursement of funds for exceptional needs such as the establishment of facilities for the isolation of patients or the payment of a reward for reporting cases. These and similar fiscal problems were largely resolved by the use of WHO funds to meet the "local costs" mentioned above. Their use was

facilitated by establishing imprest accounts, which were an advance made to WHO advisers and senior national staff, for which they had to account before a further advance was made. The availability of ready cash in this way permitted action to be taken expeditiously and eased the work in the field. Implementation of the system was not without problems, however. For example, in many areas illiteracy made it difficult to obtain the receipts which a proper accounting called for, and in all programmes there were a host of questions as to what constituted proper expenditure. The propriety might be questioned, for instance, of making small payments to smallpox-afflicted beggar families in India to ensure that they remained in isolation. Without the sympathetic and flexible administrative support provided by WHO, satisfactory solutions would seldom have been found.

#### *Operational tactics and strategy*

An important principle underlying the operation of the smallpox eradication programme as a whole was that the administrative structure and pattern of operations of each national programme should be integrated as well as possible into the health and socio-cultural setting of the country concerned. This differed from the operational strategy in malaria eradication, which called for a separate malaria service and laid down detailed administrative responsibilities and functions for personnel at every level. For smallpox eradication, the operational objective was broadly identified: the ultimate goal was a nil incidence of smallpox, to be confirmed by an adequate surveillance programme. To achieve this, a two-part programme was stipulated. First, a vaccination campaign was recommended to ensure a level of immunity among the population as a whole high enough to reduce the incidence of smallpox substantially; secondly, a surveillance programme was to be established to ensure prompt reporting of cases from all health facilities, to permit the investigation and containment of outbreaks and to analyse patterns of occurrence of smallpox so that corrective measures could be taken in both vaccination and surveillance activities.

Programmes were expected to be designed locally by the national staff and their WHO counterparts working in collaboration and to evolve and change with time in the light of

experience. Consequently, programmes differed greatly from country to country and from time to time. The role of the WHO staff assigned to the countries likewise differed somewhat from one country to another. The most effective were those who served as working counterparts and took an active role in field operations. Those who assumed the more traditional role of passive technical advisers and rarely travelled outside the capital city were encouraged to leave the programme. As working counterparts, WHO staff with prior experience in other smallpox eradication programmes transmitted confidence in the feasibility of eradication and were better able to introduce new methods; they frequently served to provide continuity and sustain momentum in programmes when the national leadership changed; and it was sometimes easier for them than for their national counterparts to approach the more senior health officials in the country to seek additional support or changes in policy.

Given this operational strategy, the WHO smallpox eradication staff in Geneva viewed as their first priority a duty to anticipate and to be fully responsive to national programme needs and to provide all possible support to them. An immediate response to requests for resources or advice, continuing communication regarding progress and developments, and frequent contact through visits and meetings were essential elements. In consequence, those who served with the smallpox eradication programme, whether as national officials or as WHO staff or consultants, identified as much with international as with national goals; they related closely to each other; and they sustained a remarkably high level of morale despite incredibly arduous working conditions. Although a pattern of programme management such as this would appear only logical, surprisingly few multinational health programmes currently operate with this philosophy.

Global strategy and priorities were regularly discussed and decided at meetings with regional and national advisers and national programme staff. Forums such as these were valuable as it was in the course of executing national programmes that the most important observations were made, as a result of which significant changes in strategy and tactics were introduced. These international meetings provided opportunities for critical discussion of the experiences communicated,

for a comparison of observations, and for the charting of new directions.

The target of a nil incidence of smallpox—the completion of a finite task—undoubtedly played a role in motivating staff and sustaining interest. There are few health programmes which have such a clearly definable end-point. However, comparable levels of achievement, interest and morale in other programmes should be possible where specific goals are clearly identified, where progress is regularly monitored and where the programme staff are fully supported and encouraged in their efforts.

### Research

The importance of the problem-oriented applied and basic research that was conducted throughout the course of the smallpox eradication programme cannot be too emphatically stated. The nature and extent of the research agenda could not at first be fully elaborated or foreseen. The most explicit question when the programme began was whether there was a natural reservoir of variola virus which could thwart the objective of eradication. Beyond this, there was the belief that studies conducted during the execution of programmes could do much to elucidate the epidemiology of the disease and to benefit programme implementation. There was, moreover, the belief that the potential of the tools and methods already available could be further developed to permit the task to be achieved faster and more efficiently.

What was not anticipated at the inception of the programme was the extent to which changes would occur in programme strategy and tactics and in the understanding of the epidemiology and virology of smallpox and other poxviruses. Contributions to these changes were made in a range of disciplines, extending from basic molecular biology to applied technology and the social sciences. The research agenda did not, however, unfold spontaneously. Smallpox eradication programme staff and consultants met regularly to discuss developments and needs. Many staff had to be encouraged and sometimes prodded to explore important questions. Substantial time and effort were expended in editing and preparing for publication many of the papers which were eventually distributed.

The fact that most research was undertaken during and in the context of the field work in

order to answer practical questions or to resolve apparent paradoxes provided an unusual impetus to the research effort. Moreover, the interaction of research and programme execution permitted the prompt practical application of many of the findings.

The lesson for other disease control programmes seems evident. However, even today, despite countless discussions about the importance of research for smallpox eradication, other problems of importance to the developing countries receive little research support. Research in applied technology and the social sciences is notably neglected and the potential offered by modern molecular biology has barely begun to be realized. For health programmes in the developing countries, research is neither an academic luxury nor merely an interesting intellectual exercise, as has sometimes been suggested. It is a necessity for the successful prosecution of disease control and was inherent in the achievement of the goal of smallpox eradication.

### Certification

A feature peculiar to smallpox eradication was that, once it had been achieved, health officials throughout the world—and the general public—all had to be sufficiently confident of the fact that the disease had been eradicated everywhere for them to abandon the practice of vaccination. To instil the necessary conviction, special certification activities were required; they are not without relevance to other situations in which one country's policy is shaped by the health conditions in other countries.

Fostering the required confidence presented difficulties at many levels. National authorities everywhere recognized that the reporting of infectious diseases was deficient in all countries and that in certain circumstances some governments suppressed information about known cases of smallpox (see Chapters 22 and 23). Within countries, smallpox vaccination, one of the oldest public health measures, was a well-established practice, not lightly to be discarded by those responsible for their country's health. The general population of the endemic countries readily recognized smallpox, and in many cultures it was so familiar as to be considered an inevitable occurrence of normal life. Continual efforts were made by the smallpox

eradication programme to publicize widely and in detail, both in the scientific and the general press, what was being accomplished and how. Accounts of the work appeared in WHO's *Weekly epidemiological record*; comprehensive summaries were prepared each year for the World Health Assembly and the Executive Board of WHO; numerous scientific papers were published; and coverage in the public media was actively solicited. These efforts intensified as the goal of eradication approached and was finally reached. Although they were partly successful in convincing many persons that the programme had been well conducted and that WHO and national officials spoke with justified confidence of the accomplishment, more was required.

In 1971, the decision was made to appoint independent international commissions of recognized scientists to visit each country in the endemic areas 2 years or more after the occurrence of the last known case so that they might satisfy themselves that the measures taken by the programme would have detected smallpox had it been present. If they were not satisfied, they were directed to recommend additional measures which should be taken. Such visits were arranged only when WHO and national staff were themselves confident that smallpox had been eradicated from an area and that the fact could be documented. Confidence in the process was enhanced when most countries followed a precedent set by Indonesia during the visit of the second of the commissions (early in 1974), when the members of the commission were informed that they could go anywhere they wished, that they could have access to any records they wanted and that they could question anyone about any matter pertaining to smallpox and the eradication programme (see Chapter 13). The first of the international commissions was convened in 1973; altogether, 22 commissions visited 63 different countries (see Chapters 24-27).

There were a number of salutary features of this approach which deserve mention. First, it required each country to prepare a special report setting forth the activities and the evidence which documented the absence of smallpox; this requirement stimulated national officials to support smallpox surveillance programmes after the last case had occurred and when the inclination was strong to divert resources prematurely to other needs. Secondly, wider knowledge of the

nature of the programme and confidence in its success were gained by involving in the commissions scientists of many different nationalities, including those who were most sceptical. Thirdly, when each commission reached a decision that eradication had been achieved, important opportunities were presented to publicize the fact nationally and internationally.

A global commission, composed of 22 scientists from 20 countries and assisted by 9 advisers from 7 countries, surveyed the status of the programme from a world-wide perspective and recommended other activities which they believed were needed for them to be confident that eradication had been achieved. Although some activities involved special studies in areas and countries to which access by international staff had been limited, all were completed or satisfactory alternative measures devised and conducted.

Certification of smallpox eradication was valuable and necessary in giving the world community confidence in the achievement. Like the eradication programme itself, it was designed specifically to meet this need and cannot serve as a template to be applied to other questions in which mutual confidence among nations is essential for deciding sound policy. However, problems arising from national doubts about the status of conditions in other countries have arisen in the past and can be expected in the future. Such problems have included those pertaining to the acquired immunodeficiency syndrome (AIDS) and cholera, as well as natural and man-made environmental contamination involving chemicals and nuclear materials. In such circumstances, certain of the principles of the certification programme have applicability—specifically, assessment of the problem in question under the auspices of an international organization, the use of respected scientists of different nationalities who are requested to be critical in judgement, and open publication of their observations and conclusions.

## COSTS AND BENEFITS

The eradication of smallpox marked the end of the pain and suffering of its victims who, as recently as 1967, are estimated to have numbered 10-15 million each year and among whom probably 1.5-2 million died. It marked the end of the severe disfigurement, blindness and other disabling conditions

among those who survived. It meant that all countries could utilize their smallpox hospitals and wards for other health purposes, that they could stop vaccination programmes and that travellers would no longer need to present vaccination certificates attesting that they had been successfully vaccinated.

The existence of smallpox had important financial implications for all countries. In 1967, all countries were expending substantial funds either to control smallpox and to care for its victims, as was the case in the endemic countries, or to vaccinate and operate quarantine programmes to prevent the disease from being imported, as was the case in countries which were free of endemic smallpox. The expenditure of considerably greater sums for further therapeutic or quarantine services would have accomplished little. However, modest additional expenditures for the prevention of smallpox made a dramatic difference. For the entire global smallpox eradication programme, the annual costs, on average, amounted to only US\$23 million over the 13-year period, 1967-1979, a sum which includes both national costs and international contributions.

The benefits to all countries of eradicating smallpox would appear so great and so clear that it is difficult to understand why there were problems in obtaining the requisite resources and political commitment. In part, this reflects the fact that governments tend to be more immediately and generously responsive in providing for the immediate needs of those who are ill. As a practical reality, patients express gratitude for the services received and political support for those providing them. Preventive services are less appealing, the results being reflected in impersonal statistics which indicate that there are fewer or perhaps no patients. An equally important problem is the fact that measures for disease prevention usually require a long period of sustained support and attention before results become apparent. Unfortunately, government officials and donor organizations customarily conceive of plans and budgets in blocks of 3-5 years. Longer-term commitments are uncommon, and with changes in leadership different initiatives are pursued. Even for smallpox eradication, which required comparatively small resources, it proved difficult in most countries to sustain the interest of both national governments and international agencies much beyond 5-6 years.

### The Cost to the Developing Countries

For the endemic countries, data regarding the cost of smallpox control programmes are few, and estimates of the expenditure on the care of patients and of the economic losses in productivity due to death or illness are available only for India. No known data document the cost of rehabilitation for those who were left blind or otherwise handicapped.

In 1967, the cost of smallpox control programmes consisted primarily of expenditure on vaccination, i.e., the cost of vaccine, personnel and transport. For the developing countries, this amounted to about US\$0.10 per vaccination performed (World Health Organization, 1966b). From national programme reports, it is estimated that a number equivalent to about 20% of the 2500 million residents of the developing countries was being vaccinated each year. This would suggest that about US\$50 million were being expended annually for vaccination (Table 31.1).

The costs of care for those who developed smallpox were computed in a study in India by Ramaiah (1976a), who calculated an average expenditure of US\$2.85 per patient. Assuming, as he does (Ramaiah, 1976b), that about 2% of all cases were being reported in India in 1967, the total cost of patient care for that year in India alone would have been US\$12 million. Given the fact that India, in 1967, accounted for 64% of all reported cases in the world, it would seem reasonable to estimate the cost of patient care globally at more than US\$20 million.

Losses due to diminished economic productivity as a result of death must also be considered. For India, during 1967, they are calculated to have been about US\$700 million.

Table 31.1. Estimated cost of smallpox to the developing countries, 1967 (millions of US\$)<sup>a</sup>

	India	All developing countries
Smallpox control through vaccination	10	50
Care of smallpox patients	12	> 20
Loss from diminished economic productivity	700	> 1 000
Total	722	> 1 070

<sup>a</sup> Because the most comprehensive data are from India (Ramaiah, 1976a,b; Basu et al., 1979), these are given separately, the figures for all developing countries being extrapolated from those for India. Among a total population of 1079 million persons in the endemic countries in 1967, 513 million (48%) lived in India.

The calculation is based on Ramaiah's analysis (1976a), which employs a life-table approach and defines economic productivity in terms of expected excess of income over consumption during the individual's lifetime. However approximate the calculation, the average loss in economic productivity of about US\$825 per death would appear conservative. Extrapolated globally for perhaps 1.5 million deaths which were estimated to have occurred in 1967, it would seem reasonable to assign a value of at least US\$1000 million.

Loss of productivity due to the 3-4 weeks of incapacitation associated with illness must also be considered although in India this was found to be small (Ramaiah, 1976a), mainly because a large proportion of cases were in children for whom no loss in productivity was assumed, and, in part, owing to the low productivity of the average worker.

From these data, sketchy as they are, the cost of smallpox to the developing countries in 1967 was substantial indeed, being not less than US\$1000 million (Table 31.1).

### The Cost to the Industrialized Countries

Almost all industrialized countries spent substantial sums of money for the routine vaccination of their own populations so that, if smallpox was introduced, the disease would not spread widely; international travellers were required to present certificates of vaccination; and at least two countries maintained special hospitals for use should smallpox be introduced.

Only one comprehensive study of the costs of smallpox prevention in an industrialized country has been reported, a study conducted in the USA in 1968 (Sencer & Axnick, 1973). The cost that year to the USA of providing 5.6 million primary vaccinations and 8.6 million revaccinations was calculated to be US\$92.8 million—about US\$6.50 per vaccination (Table 31.2). Among those vaccinated, 8024 had complications requiring medical attention, 238 were hospitalized, 9 died and 4 were permanently disabled. Other costs were associated with absences from work due to vaccination and vaccination reactions, quarantine services and time lost by the maritime industry in waiting for clearance of vessels. The average annual cost of US\$150 million amounted to about US\$0.75 per capita for 1968. These data do not permit accurate global estimates of the expenditure by all industrialized countries but, if a cost as low as

Table 31.2. Costs associated with smallpox protection in the USA, 1968 (millions of US\$)<sup>a</sup>

	Amount
Direct cost for medical services:	
Vaccination	92.8
Treatment of complications	0.7
Indirect costs, loss of productivity:	
Work losses due to vaccination and reactions	41.7
Permanent disability due to complications	0.4
Premature death	0.1
Cost of international traffic surveillance and delays in clearance of vessels	14.5
Total	150.2

<sup>a</sup> From Sencer & Axnick (1973).

US\$0.25 per capita is assumed for those other than the USA, the annual cost, for 1967, would have been US\$350 million.

### Expenditure

Compared to the annual cost of smallpox to the world which, in 1967, was more than US\$1350 million, the anticipated expenditures for a 10-year global eradication programme were modest indeed. The Director-General of WHO, in 1966, estimated a need for international assistance of US\$4.85 million per year over a 10-year period. He requested that US\$2.4 million be appropriated for this purpose in WHO's 1967 budget, although this was accepted by the World Health Assembly by only the narrowest of margins (see Chapter 9).

Ultimately, the costs of the programme were greater than had been anticipated (Table 31.3). International expenditure amounted to US\$98 million, about twice what had been foreseen. The endemic countries are believed to have spent no more than twice this amount, about US\$200 million.

For all countries, the economic benefits of the programme were substantial as it became possible to stop all preventive measures and to close treatment facilities. The USA, although the largest donor, is estimated to realize in savings the total of all its contributions to the programme every 26 days (Brilliant, 1985).

### IMPLICATIONS FOR THE FUTURE

The achievement of smallpox eradication demonstrated the potential of WHO as an organization within which all countries, whatever their beliefs and politics, could cooperate successfully in the pursuit of a

Table 31.3. Expenditure on smallpox eradication, 1967-1979 (US\$)<sup>a</sup>

	Estimated expenditure, 1967-1979	% of total
<b>International expenditure</b>		
WHO regular budget	33 565 248	11

<b>Total</b>	<b>97 969 737</b>	<b>33</b>
<b>National expenditure in the endemic countries<sup>a</sup></b>	<b>200 000 000</b>	<b>67</b>

<sup>a</sup> Based on analysis of financial data from Bangladesh, Ethiopia, India and Indonesia and less complete data from other countries which had endemic smallpox in 1967.

common global objective. It encourages the hope that other challenges might likewise be addressed. By demonstrating how cost-effective a population-wide programme for disease prevention could be, it directed attention to other preventive measures and health programmes which could effectively utilize community-wide strategies. Previously endemic countries, having become aware of the considerable capacity of their own health services when given proper direction and supervision, looked toward new goals. Thus, an important impetus was provided for new initiatives in, for example, immunization, diarrhoeal disease control and the prevention of blindness. This was by far the most significant contribution of smallpox eradication to the shaping of future strategies for the provision of health care.

Global smallpox eradication came at a time when conventional wisdom increasingly held that human pathogens were ecologically so well adapted that the concept of eradication was untenable (Dubos, 1965). However, the demonstration that the eradication of a disease was feasible led a number of scientists to conclude that this very feasibility was the most important lesson to be learned from the programme and to advocate that a similar approach should be taken to other diseases (Stuart-Harris et al., 1982). A number of diseases have been proposed as candidates, and efforts have, in fact, begun to eliminate dracunculiasis (guinea-worm infection) globally and to eradicate poliomyelitis from the Western Hemisphere.

Disease eradication is unquestionably an attractive goal, but the difficulty of its achievement should not be underestimated. It

must be borne in mind that when the smallpox eradication programme began, the prospects for its success were more favourable than for any other disease eradication programme that might be envisaged today. The technical feasibility of interrupting the transmission of the smallpox virus had already been demonstrated both in the industrialized countries and in many developing ones; an inexpensive, highly effective vaccine was available; and there was a substantial political commitment to the achievement of the goal that had been set. Nevertheless, however favourable the circumstances, success was by no means a certainty even during the concluding years or even the final months of the programme. Indeed, the gap between success and failure in a number of national programmes was a narrow one, and the issue was often favourably decided by fortuitous and unpredictable political developments and with only marginally adequate resources. It is difficult to conceive of other disease eradication programmes experiencing fewer problems; and if they were technically more difficult or less adequately and universally supported, their success would appear to be doubtful indeed.

The consequences of the failure of an eradication programme must also be weighed. Some have argued that such special efforts as would be required would result, at worst, in better control of the disease. However, the repercussions which followed upon the failure of malaria eradication cannot be ignored. Not only was the judgement and credibility of national and international leadership called into question but a number of assistance agencies decided, as a matter of policy, not to provide resources for another eradication effort. Some agencies, in fact, questioned the desirability of supporting any categorical disease programmes. These views prevailed throughout the smallpox eradication programme, often to its detriment.

### Eradiation of Other Diseases

The possible eradication of a number of diseases has been considered recently (Stuart-Harris et al., 1982) although, in the enthusiasm and interest, the proper definition of eradication has been deplorably corrupted (see Chapter 9). Some have used the term to refer to the control of a disease to the point at which it is no longer an important public

health problem and some have mistakenly applied the term to programmes intended to prevent hunger or to control accidents and injuries. Here, we refer only to the feasibility of interrupting the transmission of an infectious agent over a geographical area of sufficient size so that control measures may be stopped or greatly reduced, i.e., eradication on a regional or global scale.

The candidate diseases of greatest interest are those in which man is the only host of the pathogen and the pathogens themselves do not survive for long periods in nature or man. The prospects for eradicating diseases which have an animal reservoir—such as yellow fever, rabies or plague—are nil given present technology. Equally problematic are cholera, the vibrio of which can persist for a long time in brackish, polluted waters, and diseases such as tuberculosis and leprosy, of which the mycobacteria can remain latent in man for many decades.

Another important consideration which must be weighed in considering a disease for eradication is obtaining a sufficiently broad and sustained political commitment. Those who decide policy and the allocation of funds must perceive the disease problem to be serious enough to warrant expending additional funds; but, no less, the populations which are most affected must be sufficiently motivated to cooperate. The time required is important as well because, as was noted above, it proved difficult in all countries to sustain an interest in smallpox eradication for longer than about 6 years.

The preventive measures required for eradicating the disease in question must be inexpensive, considering the fact that international support for health programmes has never been substantial and that most developing countries are already hard-pressed to meet the needs of their existing health activities. The smallpox eradication experience must be borne in mind as, despite the relatively small budget it called for and the implications which success had for all countries, the difficulty of having adequate funds available was a major constraint.

Finally, the methods to be used for the eradication of a disease should be comparatively simple to apply and should not require frequent, repeated contacts with individuals in the population. Skilled management in the developing countries is not plentiful, and programmes that require complicated procedures or considerable discretionary judge-

ment are less likely to succeed than simpler ones. Problems can also be anticipated if it is necessary to contact the population on repeated occasions, as would be the case if individual subjects had to be given a drug each day or each week for a period of weeks or months. The cost and discipline required to execute such programmes make them prohibitive in most areas.

The prospects at present for the global eradication of most human diseases are not good. Epidemiological characteristics preclude many from consideration, while the nature and cost of the available technologies rule out others. However, with a growing international interest in prevention programmes and the emergence of new and better vaccines and other technological developments, there is hope that other global eradication programmes may eventually be successfully mounted. During recent years, 4 diseases have been seriously advanced as candidates for global eradication within the foreseeable future: measles (Hopkins et al., 1982; Katz et al., 1983), poliomyelitis (Horstmann et al., 1984), dracunculiasis (Hopkins, 1983b), and yaws (Hopkins, 1976; Burke et al., 1985). In 1985, the Pan American Health Organization approved a regional poliomyelitis eradication programme, the objective of which is the interruption of poliovirus transmission in the Western Hemisphere by 1990. In 1986, a programme for the global elimination of dracunculiasis was approved by the Thirty-ninth World Health Assembly (resolution WHA39.21) although no time limit was established for its accomplishment. The prospects for each of these initiatives are briefly reviewed below.

### *Measles*

The possibility of measles eradication is suggested by the fact that man is the only host of the virus and that a single dose of an inexpensive vaccine provides long-lasting immunity in 90–95% of vaccinated persons. In developing countries, measles is a sufficiently serious disease to warrant an eradication programme. In the industrialized countries, however, complications and deaths associated with measles are so much less frequent that many countries do not now conduct effective control programmes. The wisdom of this policy has to be questioned but, certainly, there is not yet universal interest in the control of the disease, let alone

in its eradication. There are other impediments as well. The measles virus is much more readily transmitted from person to person than was that of smallpox. Not surprisingly, the disease spreads rapidly and widely, and a high proportion of children in developing countries experience measles before they reach 3 years of age. Because the virus spreads so easily and the diagnosis may present difficulties, surveillance-containment measures such as were used in smallpox eradication have not proved to be feasible or effective. To interrupt transmission, it has been calculated (Anderson & May, 1983) that an immunity level greater than 90% will be necessary, a level which is all the more difficult to achieve because vaccination is not possible before the age of 6-12 months, when the child loses its maternal antibody. If there were a vaccine which could be administered at or shortly after birth, the prospects would certainly be better.

Practical evidence that an eradication campaign is premature is provided by the experience in the USA. There, the incidence of measles has been reduced almost to nil but, despite a commitment to interrupt transmission by 1982 and the provision of considerable resources to that end, the measles virus continues to spread.

### *Poliomyelitis*

The feasibility of eradicating poliomyelitis appears greater than that of eradicating measles. Poliomyelitis is more universally accepted as being of sufficient importance to warrant an eradication programme. Man is the only host of the virus and good protection is usually provided by both the inactivated vaccine and the attenuated live vaccine. Many industrialized countries and some developing countries have, in fact, already been successful in interrupting poliovirus transmission, mostly through use of the oral, attenuated vaccine. Some industrialized countries which have used the inactivated vaccine have also been successful.

The decision by the Pan American Health Organization to begin a regional poliomyelitis eradication campaign was preceded by national vaccination campaigns in the Americas in which the inexpensive and easily administered oral vaccine was used. In the early 1970s continuing circulation of poliovirus ceased in North America, and by 1985 the number of reported cases in the Western

Hemisphere had diminished to fewer than 1000 a year.

The eradication of poliomyelitis, however, presents a number of special problems. First, the oral vaccine is so thermolabile that refrigeration is required almost to the point of administration, and at least 3 doses are necessary for protection. Vaccination campaigns that must depend upon such a vaccine are inevitably more complex and more difficult than those in which a single dose of thermostable vaccine can be used, as was the case with smallpox. Another matter of concern is the fact that several studies suggest that the oral vaccine is less efficacious in some tropical areas than in temperate climates, although the reasons for this remain unclear. The inactivated vaccine has been suggested as an alternative but it is more costly and requires 2 doses to be given by syringe and needle, a more cumbersome method. A second set of problems concerns the development of surveillance methods by which to detect the presence of circulating poliovirus. Only 1 person among 1000 or more who are infected with the virus manifests paralytic disease, and such cases require confirmation by laboratory examination. The occurrence of paralytic cases signifies that poliovirus is present in an area, but their absence does not necessarily indicate the contrary because it is known that poliovirus can spread over large areas and for an unknown period of time without causing paralytic illness. Confirmation that poliovirus transmission has been interrupted is therefore difficult. A surveillance system for paralytic illness is being developed in the Americas which involves laboratory confirmation of suspected cases and community-wide containment vaccination. The efficacy of this approach in reducing the transmission of the virus and its sensitivity in detecting circulating virus remain to be determined. The experience acquired in the Western Hemisphere will determine the feasibility of eradication in other areas.

### *Dracunculiasis (guinea-worm infection)*

The elimination of dracunculiasis, a parasitic infection, was agreed upon by the Thirty-ninth World Health Assembly, in 1986, as a campaign to be conducted in association with programmes of the International Drinking Water Supply and Sanitation Decade; although the Health Assembly's resolution (WHA39.21) speaks of "elimination", it is

difficult to distinguish the intent of this from that of "eradication". The parasite, *Dracunculus medinensis*, a nematode worm that measures 35–100 cm in length when adult, lives in the skin of man, the female emerging in a painful abscess to discharge tiny larvae when the infected part of the body is immersed in water. The larvae are ingested by a minute fresh-water crustacean, *Cyclops*, that serves as an intermediate host, in which they mature and infect man when he swallows water contaminated by the *Cyclops* organisms. Interruption of guinea-worm transmission is reasonably easily and rapidly achieved either by destroying the larval form of the parasite in the water tanks and ponds where people are infected, by filtering or boiling water before drinking it or by preventing patients with infection from entering such bodies of water.

Favouring eradication is the fact that comparatively simple measures have produced a dramatic reduction in incidence and the elimination of infection in many villages and larger areas of Africa and Asia. Moreover, the population at risk is estimated to be no more than 50 million persons, almost all of whom now live in rural areas in a regional belt extending across the middle of Africa and in western India and eastern Pakistan. Finally, the disease itself is a painful, disabling one of concern to the afflicted population, and for surveillance purposes the adult worm is easy to identify.

The principal problems which can be foreseen are those of interesting donor agencies in providing support for the elimination of a tropical disease which is so little known outside the affected countries and of mobilizing national interest and support for the elimination of a disease rarely seen outside rural and often remote areas.

### *Yaws*

Yaws is a treponemal infection, transmitted from person to person, against which widespread control and eradication campaigns were mounted during the 1950s and 1960s (see Chapter 9). A single dose of penicillin effected a rapid cure and these earlier campaigns succeeded in dramatically reducing the incidence of the disease. Initially, it appeared that eradication could be easily and rapidly accomplished, but persistent low-level infections which were difficult to detect resulted in the continuation of transmission. A more concerted effort involving repeated

visits to inspect all persons in the afflicted areas was required but, as cases diminished in number, so, too, did both the national and international interest and commitment.

During recent years, there has been a resurgence of yaws in many countries of Africa and some in Asia (*Wkly epidem. rec.*, 1986a) and renewed campaigns have begun in a number of them. Although the eradication of yaws has been proposed as a possible goal, recognition of the extent and magnitude of the problem, of the practical difficulties and of the cost of implementing successful programmes has effectively muted discussion of eradication for the time being.

### Conclusion

It is apparent that the successful eradication of smallpox has had important ramifications into other areas of health work, while it also provides illuminating evidence of the need for caution in deciding upon other eradication programmes. Those who were directly engaged in smallpox eradication, and many other health staff as well, gained an understanding of the impact a community-based programme, especially one in prevention, could have, of its remarkable cost-benefit implications and of the considerable human and financial resources which could be mobilized for such an effort. Many of these persons, both in developing and in industrialized countries, are now applying that understanding in public health practice. The establishment of specific, measurable, practical goals and their use in management have begun to be introduced into national health programme objectives and into community-based health initiatives. Surveillance and sample survey techniques elaborated in the course of smallpox eradication have begun to be employed increasingly in health programme management. Throughout the world, more emphasis is being placed on programmes for disease prevention and health promotion, in respect of both communicable and non-communicable diseases, although the need for such programmes is still vastly greater than the effort that is being expended upon them.

WHO, whose role in smallpox eradication was so vital, offers a unique, although as yet not fully realized potential, for promoting these new and growing efforts. It is an organization which demonstrably can catalyse achievements far out of proportion to the

financial resources it commands. The extent to which it is successful will depend upon the confidence which its Member States place upon it, on its effectiveness in enunciating clear and measurable objectives and in mobilizing support for their realization, on the number and competence of its professional

staff, and on its ability to set aside extraneous political questions. Its ability to respond appropriately to challenges old and new will be decisive in its task of helping all the people of the world to the attainment of the highest possible level of health.

## WHO Documents in the WHO/SE, SE and SME Series\*

### WHO/SE series

- WHO/SE/68.1 Smallpox control in Indonesia during the second quarter of the century and re-establishment of endemic smallpox from 1947 (M.F. Polak)
- WHO/SE/68.2 Surveillance—the key to smallpox eradication (D.A. Henderson)
- WHO/SE/68.3 Faith Tabernacle smallpox epidemic, Abakaliki, Nigeria (D. Thompson, W. Foege)
- WHO/SE/68.4 Cultural resistance to smallpox vaccination
- WHO/SE/68.5 Characteristics of an epidemic of smallpox, Gerere Hamlet, Nigeria—1968 (J. Pifer, C.L. Adeoye)
- WHO/SE/68.6 An outbreak of smallpox in Chingleput District, Madras (A.R. Rao)
- WHO/SE/68.7 A short report on epidemiological findings of smallpox outbreaks in the city of Madras (A.R. Rao)
- WHO/SE/69.8 Field investigations of an outbreak of smallpox at Bawku, Ghana: May–October 1967 (V. De Sario)
- WHO/SE/69.9 An outbreak of smallpox in a village in Afghanistan (A.G. Rangaraj)
- WHO/SE/69.10 Some aspects of the epidemiology of smallpox in Nepal (S. Singh)
- WHO/SE/69.11 Endemic smallpox in a rural area (D.B. Thomas, W.M. McCormack, I. Arita, M. Khan, S. Islam, T.M. Mack)
- WHO/SE/69.12 "Negative" epidemiological enquiries within the framework of the smallpox eradication programme (G.F. Gloppe)
- WHO/SE/69.13 Transmission of smallpox in endemic areas (G.G. Heiner, N. Fatima, A. Ali)
- WHO/SE/70.14 An alastrim outbreak in the Gran Sabana (State of Bolívar), Venezuela, 1962 (J.G. Halbrohr)
- WHO/SE/70.15 Contribution of the French Territory of the Afars and Issas (TFAI) to smallpox control in East Africa (D. Courtois)
- WHO/SE/70.16 The efficacy and acceptability of the bifurcated needle technique: a summary of studies conducted in India

### SME series

- SME/77.1 The Nepal smallpox eradication programme: description and analysis (P.N. Shrestha, D.A. Robinson, J. Friedman)
- SME/77.2 Report of a Workshop Meeting on Safety Measures in Laboratories retaining Variola Virus, Geneva, 1-4 August 1977
- SME/78.1 Rev. 1 Operational guidelines for smallpox eradication in Somalia
- SME/78.2 Smallpox facial pockmarks [photographs]
- SME/78.3 Plan of action for the smallpox eradication programme in Somalia 1978/1979
- SME/78.6 Methodology for preparation of appropriate data for the 31 countries remaining to be certified free of smallpox (Smallpox Eradication unit, WHO Headquarters, Geneva)
- SME/78.7 Recommendations of the Third Coordination Meeting for Smallpox Eradication, Nairobi, 17-19 April 1978
- SME/78.11 Report on a visit to Ethiopia by members of the Global Commission for Smallpox Eradication, 31 May-15 June 1978 (K. Dumbell, P. Shrestha)
- SME/78.13 The eradication of smallpox in Sudan
- SME/78.14 Report on visit to the Republic of South Africa and Namibia/South West Africa, 19 January-19 February 1978 (F. Fenner)
- SME/78.15 Human monkeypox: update 1978 (J.G. Breman)
- SME/78.16 Smallpox eradication in Botswana: status report, 8 November 1978
- SME/78.17 Smallpox eradication in Swaziland: status report, 8 November 1978
- SME/78.18 Smallpox eradication in Angola: status report, 9 November 1978 (Smallpox Eradication unit, WHO Headquarters, Geneva)
- SME/78.19 Laboratory aspects of the monkeypox/white-pox virus problem (F. Fenner)
- SME/78.20 Report of informal consultation on monkeypox, whitepox and related poxviruses, Geneva, 9-10 November 1978
- SME/78.21 Worldwide smallpox eradication: last known foci and global certification (I. Arita)
- SME/78.22 Smallpox vaccine stocks (Smallpox Eradication unit, WHO Headquarters, Geneva)
- SME/78.23 Smallpox eradication in the Yemen Arab Republic: status report, November 1976 (Department of Preventive Health Services, Ministry of Health, Sana'a, and WHO Operations Officer, Smallpox Eradication Programme)
- SME/78.24 Assessment of activities in preparation for the certification of smallpox eradication in Angola: visit report, August 1978 (C.H. Tigre)
- SME/78.25 Laboratories with variola virus stocks (Smallpox Eradication unit, WHO Headquarters, Geneva)
- SME/78.26 Report to the Global Commission for Certification of Smallpox Eradication—Socialist Republic of Viet Nam, Annex 6
- SME/78.27 Smallpox eradication in the Republic of Djibouti: status report, 23 November 1978
- SME/79.1 A study of smallpox transmission rate in Bangladesh (J. Tulloch, D. Tarantola)
- SME/79.2 An evaluation of the effectiveness of smallpox surveillance and containment in Somalia (Z. Jezek, A. Deria)
- SME/79.3 Résultats préliminaires d'une enquête sur un cas de monkeypox au Nigéria (A.I. Gromyko, M. Daramola)
- SME/79.6 Report of the International Commission for Preliminary Assessment of Smallpox Eradication in Ethiopia, 3-18 April 1979
- SME/79.7 A possible case of camelpox in man (B. Kriz)
- SME/79.8 The epidemiology of measles in a rural community in Somalia (B. Kriz, A. Deria)
- SME/79.9 Report of meeting of the study group on orthopoxvirus research, Atlanta, 26-28 June (co-sponsored by WHO and CDC)
- SME/79.10 Special report on smallpox and its eradication in Yunnan Province, China (Department of Health, Yunnan Province)
- SME/79.11 Report on a visit to the People's Republic of China to consider matters relating to the certification of smallpox eradication, 14-30 July 1979 (F. Fenner, J.G. Breman)
- SME/79.12 Nomadic population movement in south-western Somalia and its influence on the planning of smallpox surveillance (B. Kriz, R. Hatfield)
- SME/80.1 Residual facial skin changes in varicella patients (Z. Jezek, W. Hardjotanojo, A.G. Rangaraj)
- SME/80.2 Supplément: Recommandations concernant les premières mesures à prendre en présence de cas suspects ou confirmés de fièvre de Lassa
- SME/80.3 Conférence-atelier sur la surveillance de monkeypox et fièvres hémorragiques virales, 28 avril-3 mai 1980, Brazzaville
- SME/80.4 Places visited and persons examined in preparation for and during visits by International Commissions for the Certification of Smallpox Eradication (Smallpox Eradication unit, WHO Headquarters, Geneva)
- SME/80.5 Lassa fever update (J.B. McCormick)
- SME/80.6 A system of surveillance for monkeypox and haemorrhagic fever (J.B. McCormick)

SME/80.7 An estimation of past smallpox incidence in South-western Somalia (B. Kriz)

SME/80.8 Biosafety procedures (V.R. Oviatt)

SME/80.9 World smallpox situation, 1967-1977 (Smallpox Eradication unit, WHO Headquarters, Geneva)

SME/80.11 Surveillance of Ebola/Marburg fevers (D.I.H. Simpson)

# INDEX OF NAMES\*

- Aasbi, Jalal M. (Saudi Arabia), 1131, 1145, 1146, 1220, 1221, 1247, 1262
- Abdulle, M. A. (Somalia), 1247
- Abou-Gareeb, A.H. (Egypt), 1148, 1167, 1171, 1202
- Achari, A.G. (India), 766, 774, 1181
- Ademola, G. Adeyemi (Nigeria), 857, 882, 884
- Adeoye, P.O. (Nigeria), 884
- Adetosoye, J.I. (Nigeria), 884
- Agbodjan, P. (Togo), 1141, 1171
- Aggarwal, Mussudi Lal (India), 740
- Agle, Andrew Nils (USA), 834, 837, 889
- Ahmed, A.M. (Somalia), 1247
- Ahmed, Zein (Ethiopia), 1020
- Ahrun, 212, 214, 218
- Aisin-Chuehi-lo Fu-lin, Emperor of China, 226
- Akhmeteli, Mikhail A. (USSR), 408
- Al Aghbari, Mohamed Kaid (Yemen), 1000, 1001, 1051, 1062, 1181
- Alam, A.M.H. Nurul (Bangladesh), 1192
- Alaso, H. (Somalia), 1247
- Alauddin, Sarder (Bangladesh), 1192
- Al-Awadi, A.-R. A. (Kuwait), 1136, 1137
- Alécaut, Alexandre Bangoura (Guinea), 898
- Alemayehu, Endale (Ethiopia), 1022
- Alemu, Tadesse (Ethiopia), 1244
- Algan, Celal (Turkey), 438, 959, 960, 961, 963, 1062, 1113, 1148, 1163, 1167, 1171, 1202, 1293
- Ali, Ashgar (Pakistan), 687
- Ali, Mobarak (Bangladesh), 1192
- Ali, Nayeb (Bangladesh), 1192
- Ali, Sarafat (Bangladesh), 1192
- Alima, D.W.O. (Kenya), 1062, 1231
- Al-Razi (Rhazes), 213, 214, 215, 218, 225, 229
- Altman, Lawrence K. (USA), 450, 452, 854
- Altmann, Moises (Argentina), 1171, 1202, 1203, 1204
- Amaral, Claudio do (Brazil), 619, 620, 1029, 1030, 1031, 1032, 1231, 1234, 1236, 1244
- Ambwani, G.J. (India), 735, 736
- Amherst, Sir Jeffery, 239
- Anoez, Hasan (Indonesia), 639
- Arbani, Poerwokoesoemo R. (Indonesia), 644, 702, 1027, 1231, 1236
- Arevshatian, Leva A. (USSR), 1163
- Arita, Isao (Japan), 408, 410, 414, 418, 431, 433, 473, 480, 543, 550, 551, 558, 741, 744, 745, 762, 814, 817, 903, 1045, 1051, 1054, 1062, 1097, 1131, 1148, 1167, 1171, 1185, 1202, 1207, 1210, 1229, 1231, 1232, 1236, 1237, 1247, 1250, 1252, 1261, 1277, 1283, 1285, 1293, 1306, 1334
- Arita, Isao (*cont.*)
- Arnt, Nilton (Brazil), 611, 821, 822
- Arora, Ram Rakha (India), 755, 762, 1181
- Asaduzzaman, M. (Bangladesh), 1192
- Aujaleu, E.J. (France), 415
- Aung Myat (Burma), 1192
- Avicenna, 214, 225
- Awad, I.O. (Somalia), 1247
- Axell, Seve O. (Sweden), 917
- Azurin, Jesus (Philippines), 1131, 1146, 1262
- Banu, Rahima (Bangladesh), 844, 845, 848
- Bari, M. (Bangladesh), 1191
- Bashar, A.U.M. Khairul (Bangladesh), 1192
- Bassett, David C. (USA), 796, 1214
- Basu, Rabinder Nath (India), 751, 756, 1131, 1145, 1146, 1180, 1187, 1192, 1219, 1225, 1226, 1244, 1246, 1247, 1262
- Baxby, Derrick (United Kingdom), 1313
- Bédaya-Ngaro, Simon (Central African Republic), 1141, 1167
